► **Radiation therapy (XRT).** Early post-op radiotherapy has been debated as an adjunct. It has been shown to prolong median progression-free survival from 3.4 to 5.3 years but does not affect overall survival.[76] Quality of life and cognition were not assessed. Typically given as 54 Gy in fractions of 1.8–2 Gy over 5–6 weeks. In patients with radical tumor resection, early RT did not prolong PFS and is recommended to be deferred until progression. Following incomplete resection, early RT significantly prolongs PFS and disease-specific survival.[77] Two prospective trials found no difference in OS or PFS between different XRT doses (EORTC trial[78]: 45 Gy in 5 weeks vs. 59.4 Gy in 6.6 weeks; Intergroup study[79]: 50.4 vs. 64.8 Gy). Side effects from whole brain XRT (WBXRT) include leukoencephalopathy and cognitive impairment (see Radiation injury and necrosis (p. 1899)). The frequency of side effects may[79] or may not[80] be higher at higher XRT doses.

► **Chemotherapy .** Usually reserved for high-risk patients or low-risk patients with tumor progression. RTOG 9802 showed benefit of PCV (p. 628) in PFS and OS in IDH-mutant, grade 2 astrocytomas,[69] but not for IDH-wildtype.

Temozolomide (Temodar®) initially appeared to be effective in progressive AIM grade 2 tumors (off label use).[81]

37.5.4 Treatment of diffuse gliomas, grades 3 & 4

Tumors included in this section

- astrocytoma, IDH mutant grades 3 & 4 (AIM grades 3 & 4)
- oligodendroglioma, IDH-mutant, 1p/19q codeleted grade 3 (ODG grade 3)
- glioblastoma, IDH-wildtype (GBM)

Surgery for newly diagnosed AIM grade 3 & 4 and glioblastoma, IDH-wildtype

See section 37.5.2.

Maximal safe cytoreductive surgery followed by external beam radiation and concurrent temozolomide has become the standard against which other treatments are compared.[82]

Adjuvant therapy for diffuse glioma grades 3 & 4

Stupp regimen

General information

The standard of care for newly diagnosed grade 3 & 4 gliomas is cytoreductive surgery followed by the "Stupp regimen"[82] which consists of concomitant and adjuvant radiotherapy and chemotherapy as detailed below. Chemoradiotherapy is started within six weeks after histological diagnosis. Alkylating agents (the current prototypical drug is temozolomide) are more effective in tumors that are deficient in the DNA repair enzyme, MGMT (see below for details).

Radiotherapy (XRT) in the Stupp regimen

XRT in the Stupp regimen consists of fractionated *focal* radiation at a dose of 2 Gy per fraction once daily five days per week over a period of six weeks, for a total dose of 60 Gy, with a 2–3 cm margin of clinical target volume. This is compared to the previous conventional XRT regiment for malignant gliomas of 50–60 Gy (usually 50 Gy to a margin 2–3 cm greater than the enhanced volume on MRI with a boost to the enhancing volume to bring the total to 60 Gy[83]).

Chemotherapy in the Stupp regimen

Concomitant chemotherapy employs temozolomide (TMZ), an oral alkylating agent that is a prodrug which undergoes rapid non-enzymatic conversion at physiologic pH to the active metabolite monomethyl triazenoimidazole carboxamide (MTIC). The cytotoxic effect of MTIC is associated with alkylation (primarily methylation) of DNA at various sites, including the O^6 and N^7 positions on guanine.

Temozolomide dosing

- initial treatment: 75 mg/m^2/day, 7 days per week till the end of XRT
- 4 weeks later, start 6 cycles of *adjuvant* chemotherapy with each cycle consisting of 5 days of TMZ repeated every 28 days
  - first cycle dosing: 150 mg/m^2/day
  - subsequent cycles dosing: 200 mg/m^2/day

Side effects: Temozolomide may cause myelosuppression. It should not be given unless the neutrophil count is ≥ 1.5 x 10^9/L and platelet count ≥ 100 x 10^9/L. For all patients with newly diagnosed high-grade gliomas for concomitant TMZ and radiotherapy, prophylaxis against *Pneumocystis jirovecii* (formerly *P. carinii*) pneumonia is required for the initial 6-week regimen.

Adjuvant monotherapy with TMZ is also associated with malignant transformation in low grade diffuse gliomas on multivariate analysis.[84]

▶ **MGMT transcriptional silencing (epigenetics).** Alkylating chemotherapeutic agents (p. 627) (e.g., nitrosourea or temozolomide) damage DNA by attaching an alkyl group (the smallest of which is a methyl group) to guanine bases forming O^6-methylguanine which results in cell death. **MGMT** (O^6-methylguanine-DNA methyltransferase) is a DNA repair enzyme that specifically removes this cytotoxic alkyl group and restores guanine residues to their native state.[85,86] Compared to normal cells, ≈ 75% of grade 4 AIMs inherently have reduced MGMT activity (while only 36% of GBM, IDH-wildtype have reduced activity), most likely as a result of epigenetic transcriptional gene silencing through hypermethylation of the CpG islands (promoter areas) of the genome that codes for MGMT, located on chromosome 10q26.[87,88]

MGMT activity is an independent prognosticator for response to chemotherapy with alkylating agents. Longer survival is observed with higher grade AIMs that have reduced MGMT activity[37] (MGMT levels < 30 fmol/mg protein respond better to alkylating agents[89]).

The box below summarizes the implications of gene methylation and MGMT activity.

Notes: testing for promoter gene methylation is done by PCR (polymerase chain reaction) which is may need to be sent out to a lab which typically takes 1–2 weeks for results. Cost is in the range of $1000 U.S. Measuring MGMT is faster, but does not always produce reliable results, and requires frozen tumor specimens which may not always be available. Although methylation of > 10% of the promoter gene may be reported as "methylated," it is only when methylation is **> 30%** that the median OS with Temodar increases significantly to 25.2 months compared to 15.2 months for all others.[90] Promoter gene methylation may not be as accurate a predictor of outcome as the mRNA expression product.[89] Analysis of recurrent astrocytomas shows some tumors with methylated MGMT promoter genes may convert to unmethylated following treatment[91] (possibly as a result of Temodar toxicity giving selective advantage to resistant cells).

Σ: Transcriptional silencing of MGMT synthesis

Finding	Comment
Hypermethylation (sometimes reported simply as "methylation") of the MGMT promoter gene	This naturally occurs on chromosome 10q26 of the DNA in 75% of grade 4 AIMs. It usually leads to reduced levels of MGMT activity (see the next row in this table) which becomes very significant at > 30% methylation
Reduced (or undetectable) MGMT activity	MGMT is an enzyme that repairs the damage to DNA caused by alkylating chemotherapy drugs such as temozolomide (Temodar®). Tumors with reduced MGMT levels are more susceptible to cytotoxic effects of temozolomide than nontumor cells which have normal MGMT levels, and are better able to repair the DNA damage. This results in longer patient survival

Outcomes with the Stupp regimen

The median survival was 14.6 months with the Stupp regimen compared to 12.1 months with radiotherapy alone, with median survival benefit of 2.1 months. The five-year survival rate was 9.8% for the Stupp regimen in contrast to 1.9%.[92] Regardless of extent of resection and MGMT status, patients receiving the Stupp regimen had longer median survival. Patients with MGMT promoter gene methylation (75% of AIM grade 4 tumors, compare to 36% of GBM IDH-wildtype) had median survival time of 23.4 months compared to 12.6 months in the non-methylated group (see below). In the MGMT unmethylated group, the Stupp regimen only improved median survival from 11.8 months to 12.6 months. Some practitioners extend the adjuvant chemotherapy after the standard six-month regimen until tumor progression is observed; in one study this extended the median survival time from 16.5 months to 24.6 months.[93]

Other adjuvant treatment options for high-grade AIM and GBM

Gliadel® wafer: carmustine (BCNU) 7.7 mg in a 200 mg prolifeprosan 20 hydrophobic polymer carrier (wafer) that can be applied to resection cavity after tumor excision. The wafers are degraded by hydrolysis and the drug is released over 2–3 wks. This exposes the tumor to 113 times the concentration of BCNU compared to IV administration. Following tumor removal, up to 8 of the 1.4 cm × 1 mm (dime-sized) wafers are applied to the tumor resection bed at the time of surgery.

It increases median survival to 13.8 months compared with 11.6 months in placebo groups for newly diagnosed malignant gliomas.[94] It showed no survival benefit for recurrent disease.[95] Side effects: seizures, cerebral edema, healing complications, intracranial infection.

MRI-guided **laser interstitial thermal therapy** (LITT): This may be a consideration for patients needing treatment when surgery is not a consideration and when maximal XRT has already been given, oftentimes in the setting of radiation necrosis.[96]

Focused ultrasound (FUS) may become a non-invasive adjuvant therapy option for some deep situated tumors.[97] Transcranial FUS is not a viable option for tumors near the surface due to the inability to focus the ultrasound beams close to the convexity of the skull.

37.5.5 Response to treatment

Pseudoprogression

Since XRT + temozolomide became part of the standard of care for the treatment of many high grade difuse gliomas, there has been an increase in progressive contrast-enhancing areas on MRI that mimic tumor progression, typically seen ≤ 3 months after treatment. This phenomenon, called pseudoprogression, occurs in up to 28–60% of patients after XRT + temozolomide treatment. Histologically it resembles radiation necrosis and is believed to be associated with tumor kill by radiation. Increased tumor kill with chemotherapy results in more pseudoprogression; therefore it is more common with temozolomide treatment for tumors with methylated MGMT promoter genes (as in astrocytoma, IDH-mutant) (91%) vs. unmethylated (as in glioblastoma, IDH-wildtype) (41%).[98]

Diagnosis: There is no definitive diagnostic test to distinguish pseudoprogression from true progression or from radiation necrosis. Imaging methods that have been tried: MR perfusion, DWI with higher apparent diffusion co-efficient (ADC), MR spectroscopy, and PET have not achieved high sensitivity and specificity. Monitoring with serial MRIs and clinical exams seems to be an effective strategy. Rule of thumb: MRI changes suggestive of GBM recurrence within the first 6 months after treatment with XRT + temozolomide should be assumed to be pseudoprogression as long as it is within the radiation field.

Management: The MRI findings usually improve without treatment.[99] If significantly symptomatic, options to ameliorate symptoms include:

1. corticosteroids
2. bevacizumab (Avastin®): often used to treat radiation necrosis[100]
3. laser interstitial thermal therapy (LITT): as a salvage technique for *radiation necrosis*, LITT facilitated reduction of steroid dependency with stabilization of KPS, QOL and neurocognitive function[101]
4. ✖ hyperbaric oxygen: thus far, only case reports and small non-randomized studies support its use

Pseudoresponse

Gadolinium contrast agents used with MRI produce enhancement in areas where the blood-brain barrier (BBB) is disrupted. Just as pseudoprogression may represent increased enhancement without actual tumor regrowth (see above), agents that stabilize the BBB and thereby reduce enhancement may cause underestimation of tumor load or they may mask enhancement-free progression. This is called "**pseudoresponse**").[102] It can occur while under treatment with angiogenesis inhibitors (including agents targeting VEGF and VEGF receptors such as bevacizumab). Enhancement may also be reduced by corticosteroids (however, the effect may be variable).

RANO (Response Assessment in Neuro-Oncology) criteria

The MacDonald criteria[103] were widely used to assess response to treatment in high-grade gliomas. However, it relied on contrast enhancment on CT. Enhancement may be affected by many factors (steroids, inflammation, angiogenesis inhibitors, chemotherapy wafers, gene and viral therapies, brachytherapy…), and can therfore produce pseudoprogression or pseudoresponse (see above). As a result, the MacDonald criteria have been superceded by the RANO (Response Assessment in Neuro-Oncology)[104] criteria (▶ Table 37.6).

Table 37.6 Response Assessment in Neuro-Oncology (RANO) criteria for high-grade gliomas[a]

Complete response
Requires all of the following: 1. complete disappearance of all disease (measurable and nonmeasurable) for ≥ 4 weeks 2. no new lesions 3. stable or improved nonenhancing lesions (on T2/FLAIR) 4. patient off corticosteroids (except for physiologic replacement) 5. clinically stable or improved Patients with only nonmeasurable disease cannot have complete response (stable disease is best possible response)
Partial response
Requires all of the following: 1. (compared to baseline) ≥ 50% decrease of the sum of products of perpendicular diameters of all measurable enhancing lesions for ≥ 4 weeks 2. no progression of nonmeasurable disease 3. no new lesions 4. stable or improved nonenhancing lesions (on T2/FLAIR) on same or lower doses of corticosteroids compared to doses at baseline scan 5. corticosteroid dose at the time of the scan is no greater than dose at time of baseline scan 6. clinically stable or improved Patients with only nonmeasurable disease cannot have partial response (stable disease is best possible response)
Stable disease
Requires all of the following: 1. does not qualify for complete response, partial response or progression 2. stable nonenhancing lesions (T2/FLAIR) on same or lower doses of corticosteroids compared to doses at baseline scan 3. if steroid dose was increased for new symptoms and signs without confirming progression on imaging, and subsequent imaging shows that the need for increased steroids was due to disease progression, the last scan considered to show stable disease will be the one obtained when the steroid dose was the same as at the baseline scan
Progression
Defined by any of the following: 1. ≥ 25% increase in sum of products of perpendicular diameters enhancing lesions compared with the smallest lesion measurement at either baseline (if no decrease) or best response, on stable or increasing doses of corticosteroids 2. significant increase in nonenhancing lesions (on T2/FLAIR) on equal or increased doses of steroids compared to dose at baseline or best response after initiation of therapy not caused by comorbid events (e.g., XRT, demyelination, ischemic injury, infection, seizures, post-op changes, or other treatment effects…) 3. any new lesion 4. clear clinical deterioration not attributable to causes other than tumor (e.g., seizures, adverse effects of medication, stroke, infection…) or changes in steroid dose 5. failure to return for evaluation due to death or deterioration 6. or clear progression of nonmeasurable disease
[a]see reference[104] for definitions (e.g., measurable and nonmeasurable disease…) and for measurement technique. All lesions (measurable and nonmeasurable) must be assessed using the same technique as baseline imaging.

38 Pediatric-type Diffuse Tumors

38.1 Pediatric-type diffuse low-grade gliomas

38.1.1 Diffuse astrocytoma, MYB- or MYBL1-altered (CNS grade 1)

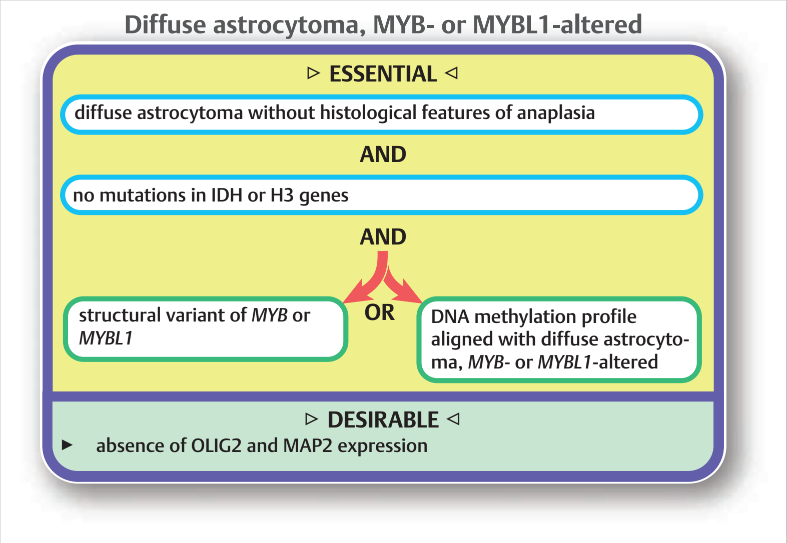
General information

See reference.[1]

A diffusely infiltrating astroglial tumor with *MYB* or *MYBL1* gene alterations.
Comprised of monomorphic cells with bland round, ovoid or spindled nuclei.
Typically presents with seizures that are refractory to medication.

Diagnostic criteria for diffuse astrocytoma, MYB- or MYBL1-altered

Diagnostic criteria are shown in ▶ Fig. 38.1.[1]



Diffuse astrocytoma, MYB- or MYBL1-altered
▷ ESSENTIAL ◁
diffuse astrocytoma without histological features of anaplasia
AND
no mutations in IDH or H3 genes
AND
structural variant of *MYB* or *MYBL1*
OR
DNA methylation profile aligned with diffuse astrocytoma, *MYB*- or *MYBL1*-altered
▷ DESIRABLE ◁
▶ absence of OLIG2 and MAP2 expression

Fig. 38.1 Diagnostic criteria for diffuse astrocytoma, MYB- or MYBL1-altered. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Subtypes

See reference.[1]

- **diffuse astrocytoma, MYB-altered**
- **diffuse astrocytoma, MYBL1-altered**

38.1.2 Angiocentric glioma (WHO grade 1)

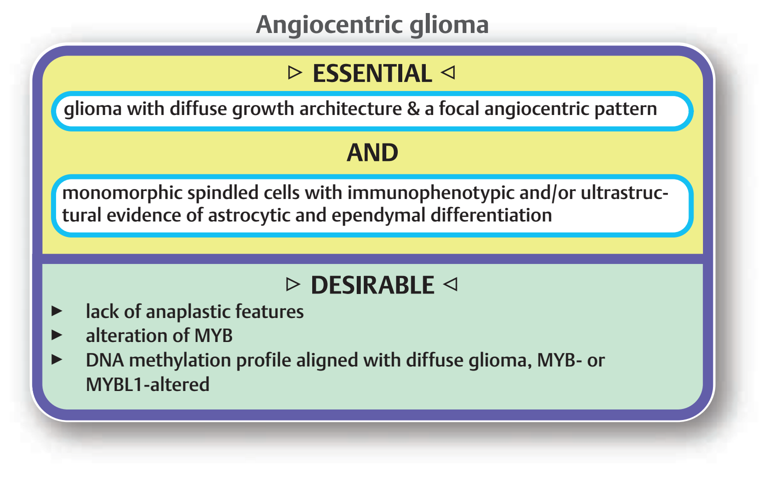
General information

A static or slow growing WHO grade 1 tumor primarily of children and young adults characterized by angiocentric pattern of growth, monomorphous bipolar cells and features of ependymal differentiation. Nearly all have *MYB::QKI* gene fusion, and the rest usually have another *MYB* alteration.

Behavior is usually indolent, with little change radiographically.

Diagnostic criteria for angiocentric glioma

Diagnostic criteria are shown in ► Fig. 38.2.[1]



Angiocentric glioma

▷ ESSENTIAL ◁

glioma with diffuse growth architecture & a focal angiocentric pattern

AND

monomorphic spindled cells with immunophenotypic and/or ultrastructural evidence of astrocytic and ependymal differentiation

▷ DESIRABLE ◁

- lack of anaplastic features
- alteration of MYB
- DNA methylation profile aligned with diffuse glioma, MYB- or MYBL1-altered

Fig. 38.2 Diagnostic criteria for angiocentric glioma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Presentation

Typically present with intractable partial epilepsy.

Imaging

Well circumscribed nonenhancing superficial or cortical based lesion typically in the temporal or frontal lobes, occasionally in the brainstem.

Treatment

Gross total excision can be achieved in most cases and is usually curative.[2]

38.1.3 Polymorphous low-grade neuroepithelial tumor of the young (PLNTY) (WHO grade 1)

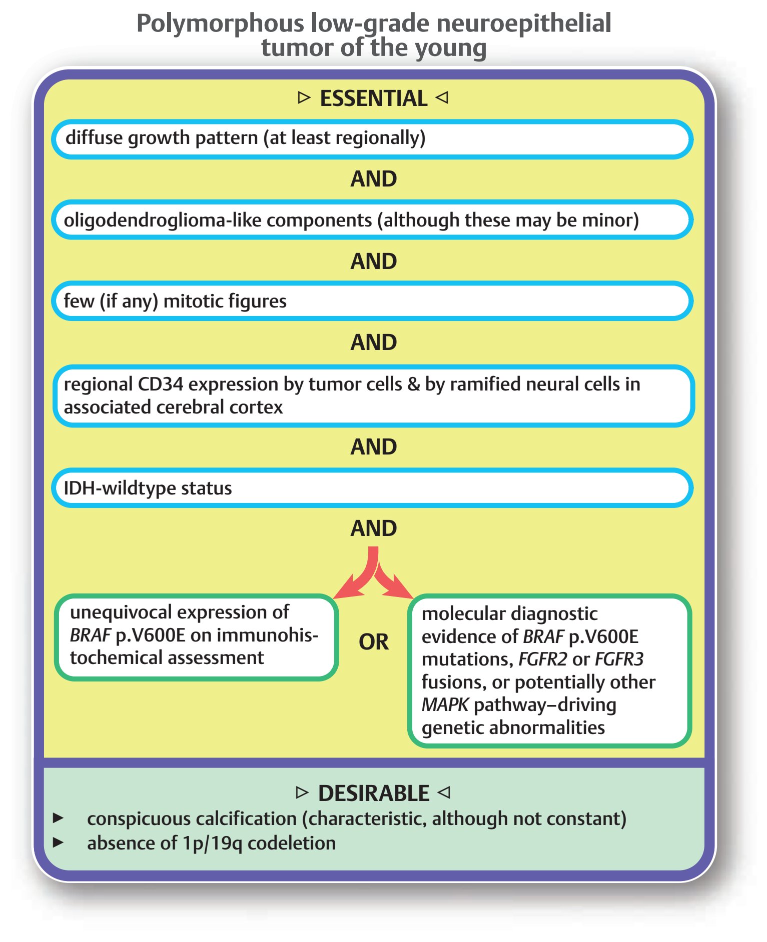
General information

An indolent tumor strongly with diffuse growth patterns, commonly with components resembling oligodendrogliomas, calcifications, CD34 immunoreactivity and MAPK pathway activating genetic abnormalities.

Behavior appears to be consistent with WHO grade 1.

Diagnostic criteria for polymorphous low-grade neuroepithelial tumor of the young

Diagnostic criteria are shown in ► Fig. 38.3.[1]



Polymorphous low-grade neuroepithelial tumor of the young

▷ ESSENTIAL ◁

diffuse growth pattern (at least regionally)

AND

oligodendroglioma-like components (although these may be minor)

AND

few (if any) mitotic figures

AND

regional CD34 expression by tumor cells & by ramified neural cells in associated cerebral cortex

AND

IDH-wildtype status

AND

unequivocal expression of *BRAF* p.V600E on immunohistochemical assessment

OR

molecular diagnostic evidence of *BRAF* p.V600E mutations, *FGFR2* or *FGFR3* fusions, or potentially other *MAPK* pathway–driving genetic abnormalities

▷ DESIRABLE ◁

- conspicuous calcification (characteristic, although not constant)
- absence of 1p/19q codeletion

Fig. 38.3 Diagnostic criteria for polymorphous low-grade neuroepithelial tumor of the young. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Presentation

Typically presents with seizures in young patients.

Imaging

Cortical and subcortical components are typical. 80% involve the temporal lobes, usually on the right side.

Treatment

Tumor excision appears to be effective and improves seizures in most cases.[3]

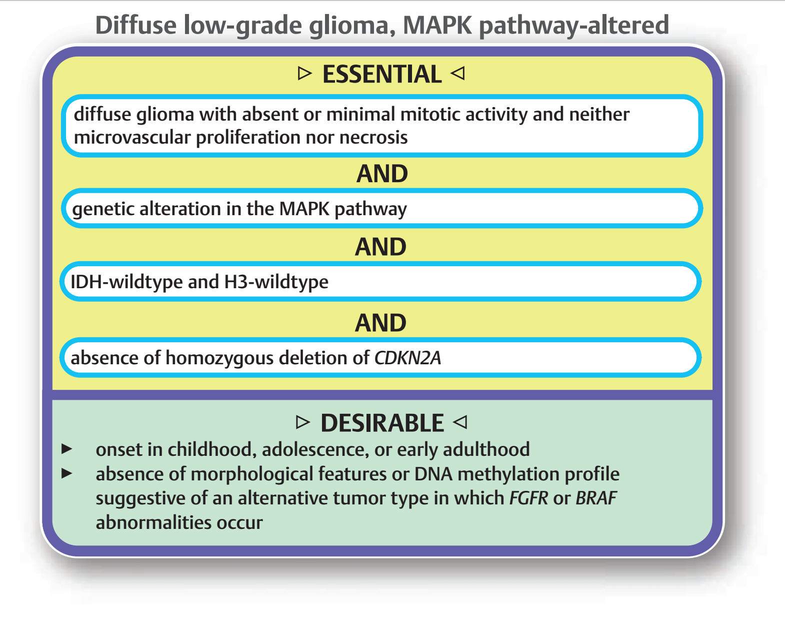
38.1.4 Diffuse low-grade glioma, MAPK pathway-altered (WHO grade 1)

General information

A low-grade glioma possessing astrocytic or oligodendroglial morphology and an abnormality in a gene coding for a MAPK pathway protein.

Diagnostic criteria for diffuse low-grade glioma, MAPK pathway-altered

Diagnostic criteria are shown in ▶ Fig. 38.4.[1]



Diffuse low-grade glioma, MAPK pathway-altered

▷ ESSENTIAL ◁

diffuse glioma with absent or minimal mitotic activity and neither microvascular proliferation nor necrosis

AND

genetic alteration in the MAPK pathway

AND

IDH-wildtype and H3-wildtype

AND

absence of homozygous deletion of *CDKN2A*

▷ DESIRABLE ◁

- onset in childhood, adolescence, or early adulthood
- absence of morphological features or DNA methylation profile suggestive of an alternative tumor type in which *FGFR* or *BRAF* abnormalities occur

Fig. 38.4 Diagnostic criteria for diffuse low-grade glioma, MAPK pathway-altered. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Subtypes

See reference.[1]

- **diffuse low-grade glioma, *FGFR1* tyrosine kinase domain–duplicated**
- **diffuse low-grade glioma, *FGFR1*-mutant**
- **diffuse low-grade glioma, *BRAF p.V600E*–mutant**

Presentation

Seizures or symptoms related to mass effect, sometimes with increased intracranial pressure.

Imaging

Appearance may resemble that of pilocytic astrocytoma complete with cystic elements, but these tumors tend to be more extensive on T2-FLAIR images.

Treatment

Unresolved issues related to the behavior of this group, and possible subgroups.

38.2 Pediatric-type diffuse high-grade gliomas

38.2.1 Diffuse midline glioma, H3 K27M-altered (WHO grade 4)

General information

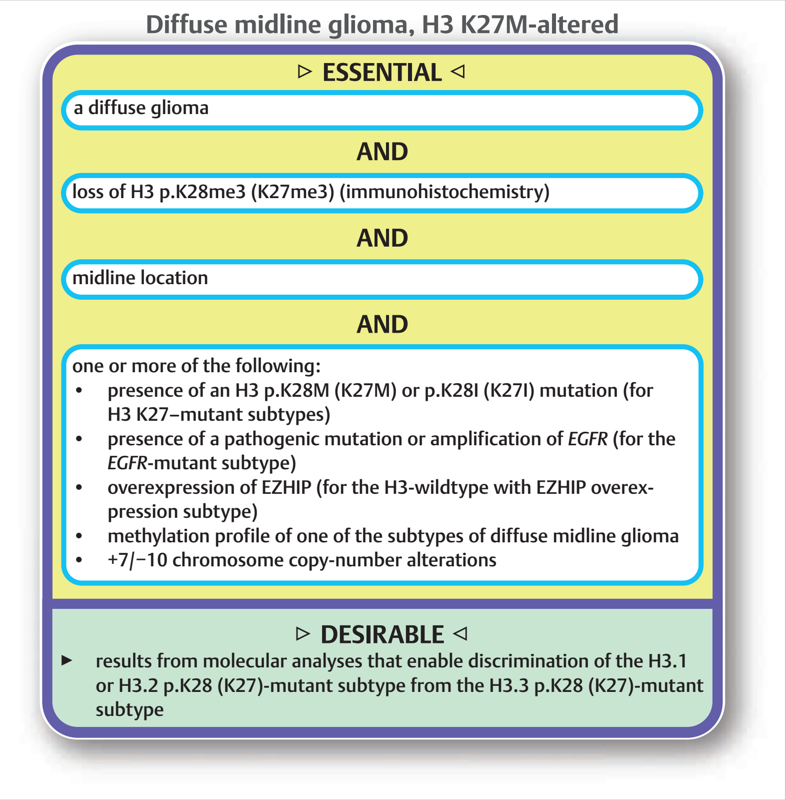
An infiltrating midline glioma with with loss of H3 p.K28me3 (K27me3) and usually either an H3 c.83A > T p.K28 M (K27M) substitution in one of the histone H3 isoforms, aberrant overexpression of EZHIP, or an *EGFR* mutation.

In children, involvement tends to be in brainstem (formerly called brainstem glioma), pons (formerly called diffuse infiltrating pontine glioma [DIPG]), or bithalamic. In adolescents or adults, they occur unilaterally in the thalamus or in the spinal cord.

Leptomeningeal involvement was found in 40% in autopsy series, and DIPG is the leading cause of brain tumor-related death in children.[4]

Diagnostic criteria for diffuse midline glioma, H3 K27M-altered

Diagnostic criteria are shown in ► Fig. 38.5.[1]



Diffuse midline glioma, H3 K27M-altered

▷ **ESSENTIAL** ◁

a diffuse glioma

AND

loss of H3 p.K28me3 (K27me3) (immunohistochemistry)

AND

midline location

AND

one or more of the following:

- presence of an H3 p.K28M (K27M) or p.K28I (K27I) mutation (for H3 K27–mutant subtypes)
- presence of a pathogenic mutation or amplification of *EGFR* (for the *EGFR*-mutant subtype)
- overexpression of EZHIP (for the H3-wildtype with EZHIP overexpression subtype)
- methylation profile of one of the subtypes of diffuse midline glioma
- +7/−10 chromosome copy-number alterations

▷ **DESIRABLE** ◁

► results from molecular analyses that enable discrimination of the H3.1 or H3.2 p.K28 (K27)-mutant subtype from the H3.3 p.K28 (K27)-mutant subtype

Fig. 38.5 Diagnostic criteria for diffuse midline glioma, H3 K27M-altered. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Subtypes

See reference.[1]

- **diffuse midline glioma, H3.3 K27–mutant**
- **diffuse midline glioma, H3.1 or H3.2 K27–mutant**
- **diffuse midline glioma, H3-wildtype with EZHIP overexpression**
- **diffuse midline glioma, *EGFR*-mutant**

Presentation

Patients with DMG typically present with a short course with brainstem findings[5] (triad: multiple cranial nerve palsies, long tract signs and ataxia) or obstructive hydrocephalus. Evidence of thalamic involvement includes signs of increased ICP, motor weakness (e.g., hemiparesis), and gait disturbance.

Evalutation

Given the high rate of leptomeningeal spread, imaging of the entire neuraxis is recommended.

Current trends favor obtaining a biopsy in most cases as ealy reports of high complications and lack of clinical utility have been debunked.[6] Biopsy confirms H3 K27M-mutation and can determine if there is MGMT promoter gene methylation.

Imaging

Pontine lesions enlarge the pons (▶ Fig. 38.6) which is low intensity on T1 and increased intensity on T2. Enhancement is minimal. Compression of the 4th ventricle may produce hydrocephalus. Encasement of the basilar artery is common. There may be an exophytic component.

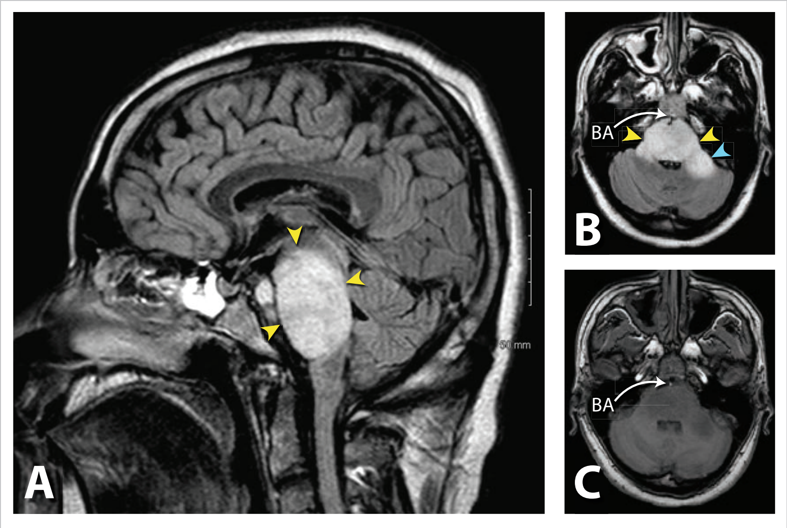


Fig. 38.6 Diffuse midline glioma, H3 K27M-altered.
Tumor is high intensity on FLAIR images and is indicated by the *yellow arrowheads*. Note the infiltration of the left cerebellar peduncle (*blue arrowhead*). Abbreviation: BA = the compressed basilar artery.
Image: MRI scans. A: sagittal FLAIR. B: Axial FLAIR. C: Axial T1 with contrast demonstrating lack of tumor enhancement.

Treatment and prognosis

Even with current therapies, 2-year survival is < 10%.[7]

The role for surgical intervention is limited due to the location of of these tumors.

Prognosis is better for subtypes involving H3.1 or H3.2 K27-mutation or EZHIP overexpression than the H3.3 K27 mutation.[1]

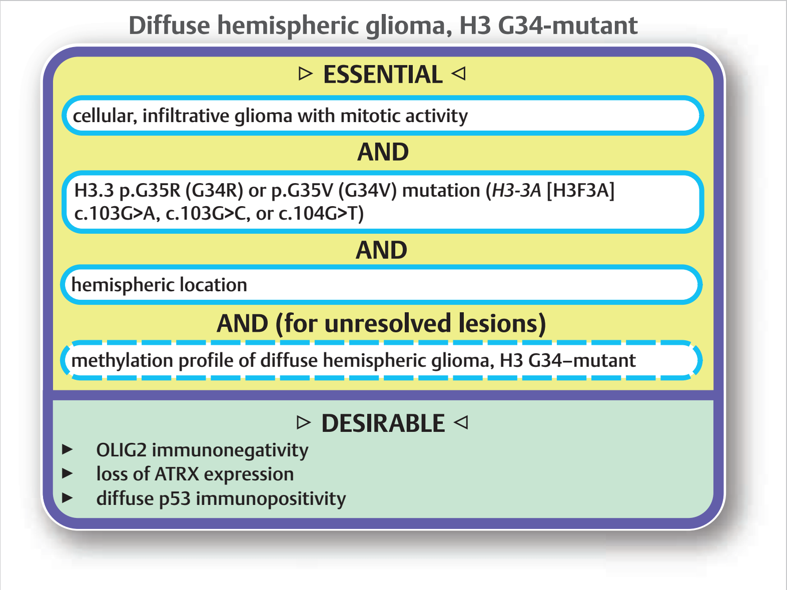
38.2.2 Diffuse hemispheric glioma, H3 G34-mutant (WHO grade 4)

General information

An infiltrative glioma located in the cerebral hemispheres having a missense mutation of the *H3-3A* gene resulting in one of the substitutions of the H3 protein shown in ▶ Fig. 38.7. The tumor occasionally extends to the midline.

Diagnostic criteria for diffuse hemispheric glioma, H3 G34-mutant

Diagnostic criteria are shown in ▶ Fig. 38.7.[1]



Diffuse hemispheric glioma, H3 G34-mutant

▷ ESSENTIAL ◁

cellular, infiltrative glioma with mitotic activity

AND

H3.3 p.G35R (G34R) or p.G35V (G34V) mutation (*H3-3A* [H3F3A] c.103G>A, c.103G>C, or c.104G>T)

AND

hemispheric location

AND (for unresolved lesions)

methylation profile of diffuse hemispheric glioma, H3 G34–mutant

▷ DESIRABLE ◁

- OLIG2 immunonegativity
- loss of ATRX expression
- diffuse p53 immunopositivity

Fig. 38.7 Diagnostic criteria for diffuse hemispheric glioma, H3 G34-mutant. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Presentation

Non specific (seizures, mass effect from locally involved brain…).

Histology

Appearance similar to GBM (high cellularity, infiltrating margins, extensive mitoses…).

Evaluation

Spine imaging is recommended in addition to brain.

Imaging

Hemispheric lesion that typically contrast enhances. Occasionally multifocal.

Treatment and prognosis

Median PFS is 9 months, with median OS of 18-22 months.[8]

Recurrence after treatment is typically local, although leptomeningeal spread may occur.

MGMT promoter gene methylation (p.673) and absence of oncogene amplification (e.g., *PDGFRA*, *EGFR*, *CDK4*, *MDM2*, *CDK6*, *CCND2*, *MYC*, *MYCN*) may portend a better prognosis for OS.[8]

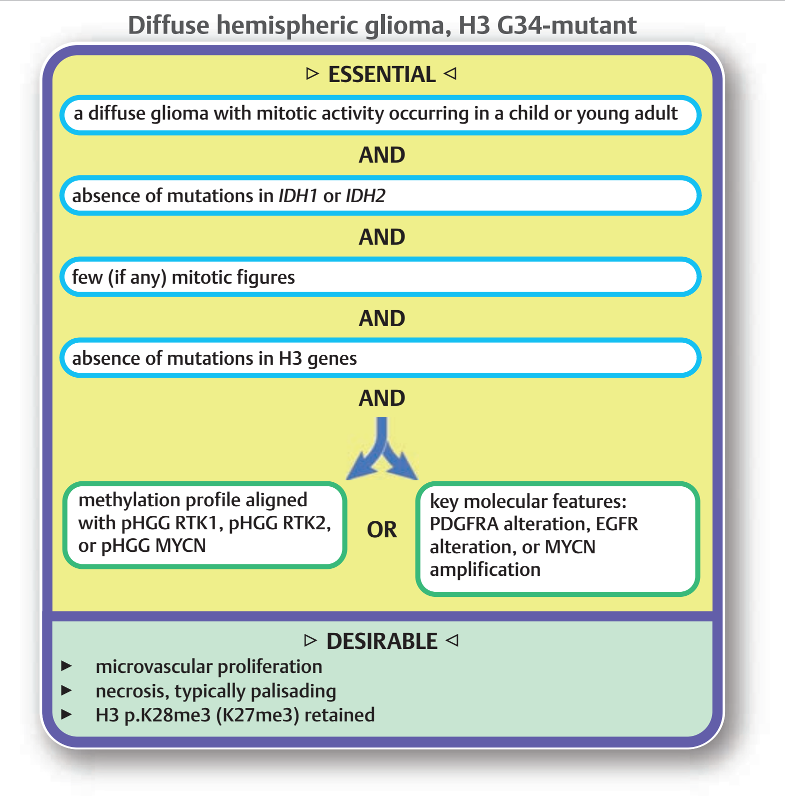
38.2.3 Diffuse pediatric-type high-grade glioma, H3-wildtype and IDH-wildtype (WHO grade 4)

General information

An infiltrative glioma located in the cerebral hemispheres having a missense mutation of the *H3-3A* gene resulting in one of the substitutions of the H3 protein shown in ▶ Fig. 38.7. The tumor occasionally extends to the midline.

Diagnostic criteria for diffuse hemispheric glioma, H3 G34-mutant

Diagnostic criteria are shown in ▶ Fig. 38.8.[1]



Diffuse hemispheric glioma, H3 G34-mutant
▷ ESSENTIAL ◁
a diffuse glioma with mitotic activity occurring in a child or young adult
AND
absence of mutations in *IDH1* or *IDH2*
AND
few (if any) mitotic figures
AND
absence of mutations in H3 genes
AND
methylation profile aligned with pHGG RTK1, pHGG RTK2, or pHGG MYCN
OR
key molecular features: PDGFRA alteration, EGFR alteration, or MYCN amplification
▷ DESIRABLE ◁
▶ microvascular proliferation
▶ necrosis, typically palisading
▶ H3 p.K28me3 (K27me3) retained

Fig. 38.8 Diagnostic criteria for diffuse pediatric-type high-grade glioma, H3-wildtype and IDH-wildtype. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Presentation

Nonspecific (seizures, mass effect from locally involved brain…).

Histology

Appearance similar to GBM (high cellularity, infiltrating margins, extensive mitoses…).

Evaluation

Spine imaging is recommended in addition to brain.

Imaging

Hemispheric lesion that typically contrast enhances. Occasionally multifocal.

Treatment and prognosis

Median PFS is 9 months, with median OS of 18-22 months.[8]

Recurrence after treatment is typically local, although leptomeningeal spread may occur.

MGMT promoter gene methylation (p. 673) and absence of oncogene amplification (e.g., *PDGFRA*, *EGFR*, *CDK4*, *MDM2*, *CDK6*, *CCND2*, *MYC*, *MYCN*) may protend a better prognosis for OS.[8]

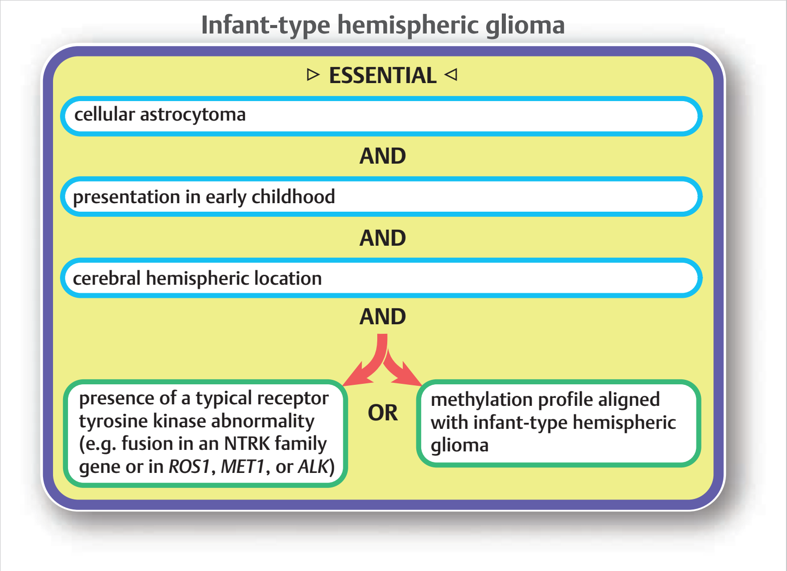
38.2.4 Infant-type hemispheric glioma (WHO grade N/A)

General information

A high-grade hemispheric glioma occurring in early childhood, having receptor tyrosine kinase (RTK) fusions inclusing those in the NTRK family, or in *ROS1*, *ALK*, or *MET*.

Diagnostic criteria for infant-type hemispheric glioma

Diagnostic criteria are shown in ▶ Fig. 38.9.[1]



Infant-type hemispheric glioma
▷ ESSENTIAL ◁
cellular astrocytoma
AND
presentation in early childhood
AND
cerebral hemispheric location
AND
presence of a typical receptor tyrosine kinase abnormality (e.g. fusion in an NTRK family gene or in ROS1, MET1, or ALK)
OR
methylation profile aligned with infant-type hemispheric glioma

Fig. 38.9 Diagnostic criteria for infant-type hemispheric glioma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Subtypes

See reference.[1]

- **infant-type hemispheric glioma, NTRK-altered**
- **infant-type hemispheric glioma, *ROS1*-altered**
- **infant-type hemispheric glioma, *ALK*-altered**
- **infant-type hemispheric glioma, *MET*-altered**

Presentation

All known cases occurred in early childhood, usually in the 1st year of life. Typically acute presentation. In infancy, may manifest as agitatin or lethargy, possibly with enlarged head circumference.

Histology

Typcially well-demarcated, cellular tumors involving brain parenchyma and leptomeninges.

Initial diagnosis was a high-grade glioma or GBM in 84%.[1]

Evaluation

Owing to leptomeningeal involvement, spine imaging is recommended in addition to brain.

Treatment and prognosis

There is insufficient data on this recently designated entity. Stereotypically, infants with high-grade gliomas fare better than older children.

39 Circumscribed Astrocytic Gliomas

39.1 General meaning of “circumscribed”

Circumscribed astrocytic tumors have a more contained growth pattern which differs from the infiltrating gliomas. With diffuse gliomas, there is generally no tumor identifiable margin beyond which there there is tumor-free brain.

39.2 Specific tumor types

39.2.1 Pilocytic astrocytomas (PCAs) (WHO grade 1)

General information

Key concepts

- a subgroup of astrocytomas (WHO grade 1) with better prognosis (10-year survival: > 95%) than infiltrating fibrillary or diffuse astrocytomas
- the most common astrocytic tumor in children
- average age is lower than for typical astrocytomas (75% of patients are ≤ 20 yrs)
- common locations: cerebellar hemisphere, optic nerve/chiasm, hypothalamus
- CT/MRI appearance: discrete appearing, contrast enhancing lesion. Cerebellar PCAs are classically cystic with mural nodule
- the principal CNS tumor associated with NF1
- histology: biphasic. 1) compacted, 2) loose (myxoid) textured astrocytes with Rosenthal fibers and/or eosinophilic granular bodies
- associated with MAPK pathway gene alterations (typically *KIAA1549::BRAF* gene fusions)
- histology alone may be inadequate for diagnosis; knowledge of patient age & radiographic appearance is critical; there is a risk of overgrading and overtreating if decisions are made on histology alone
- complete surgical resection, when possible, is usually curative. ★ For cystic PCAs with enhancing mural nodule, only the nodule needs to be resected (the cyst wall is not neoplastic). XRT is used post-op only for nonresectable recurrence or malignant degeneration

Diagnostic criteria for pilocytic astrocytoma and pilomyxoid astrocytoma

Diagnostic criteria for pilocytic astrocytoma are shown in ▶ Fig. 39.1 and for pilomyxoid astrocytoma in ▶ Fig. 39.2.[1]

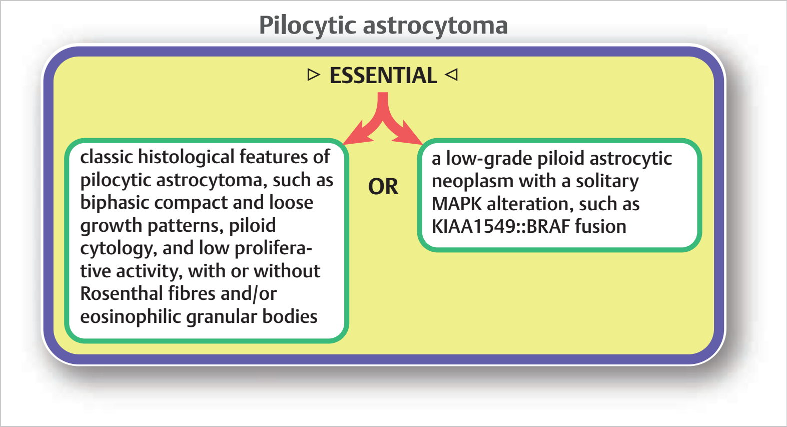
Subtypes

See reference.[1]

- **pilomyxoid astrocytoma** (PMA): a tumor of infancy that develops in the hypothalamic/chiasmatic region, and carries a higher rate of recurrence, worse outome, and tendency for CSF dissemination,[2] with a case report of extraneural peritoneal mets spread through a VP shunt.[3] Because not all PMAs behave differently than a WHO grade 1 PCA, a definite WHO grade was not recommended.[4] They are comprised of monomorphic piloid cells, have a diffusely myxoid background and increased cellularity compared with classic PCAs and angiocentric cell arrangement. By definition, does not contain Rosenthal fibers or eosinophilic granular bodies.[4] They may eventually morph into a classic PCA
  May also occur in spinal cord
- **pilocytic astrocytoma with histological features of anaplasia**: a proposed term for tumors morphologically similar to PCA but also possess mitotic features ± necrosis. These anaplastic features may be present on initial analysis, or may develop later

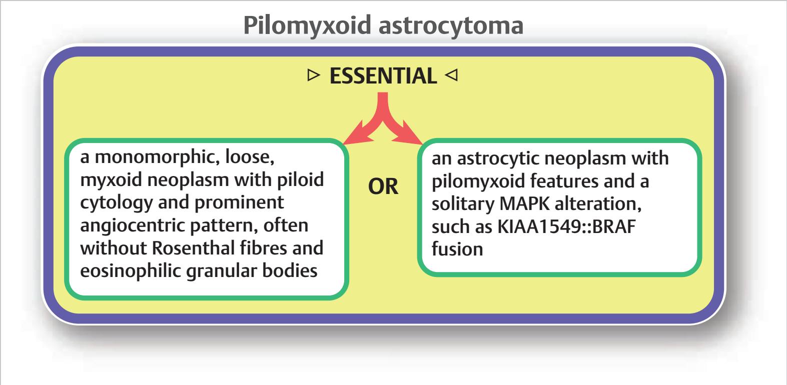
Background and terminology

Pilocytic astrocytoma (PCA) is the currently recommended nomenclature for these tumors previously referred to variously as cystic cerebellar astrocytomas and juvenile pilocytic astrocytomas



Pilocytic astrocytoma
▷ ESSENTIAL ◁
classic histological features of pilocytic astrocytoma, such as biphasic compact and loose growth patterns, piloid cytology, and low proliferative activity, with or without Rosenthal fibres and/or eosinophilic granular bodies
OR
a low-grade piloid astrocytic neoplasm with a solitary MAPK alteration, such as KIAA1549::BRAF fusion

Fig. 39.1 Diagnostic criteria for pilocytic astrocytoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)



Pilomyxoid astrocytoma
▷ ESSENTIAL ◁
a monomorphic, loose, myxoid neoplasm with piloid cytology and prominent angiocentric pattern, often without Rosenthal fibres and eosinophilic granular bodies
OR
an astrocytic neoplasm with pilomyxoid features and a solitary MAPK alteration, such as KIAA1549::BRAF fusion

Fig. 39.2 Diagnostic criteria for pilomyxoid astrocytoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

(JPA), among others.[4] Based on location, these tumors may be called optic gliomas, hypothalamic gliomas, and cerebellar PCAs. Treatment decisions vary based on location and neural involvement.

PCAs differ markedly from the infiltrating diffuse astrocytomas in terms of their reduced tendency to invade tissue and their very low propensity for malignant degeneration.

Epidemiology

PCAs comprise 5% of primary brain tumors. They are the most common glioma in pediatrics (age 0–19 years) with an incidence of 0.82/100,000.[5] The incidence progressively declines after age 15. Slight male predilection.

Usually presents during second decade of life (ages 10–20).[5] 75% occur in age < 20 years.[6]

Most PCAs are sporadic, but they are the main tumor in neurodevelopmental diseases with germline mutations in the MAPK pathway genes including: NF1 (p. 638), Noonan syndrome, and encephalocraniocutaneous lipomatosis.

Location

PCAs arise throughout the neuraxis (2003 study in adults and children[7]):

1. pilocytic astrocytoma of the cerebellum (p. 693): 42%. Formerly referred to as cystic cerebellar astrocytoma
2. cerebral hemispheres: 35%. Rare in children, tends to occur more often in older patients (i.e., young adults) than optic nerve/hypothalamic lesions. These PCAs are potentially confused with infiltrating astrocytomas possessing more malignant potential. PCAs are often distinguished by a cystic component with an enhancing mural nodule (would be atypical for a diffuse astrocytoma), and some PCAs have dense calcifications[8]
3. optic gliomas & hypothalamic gliomas: 9%
   a) PCAs arising in the optic nerve are called optic gliomas (p. 694). This is the most common site in neurofibromatosis type 1 (p. 638) (NF1) patients (may be bilateral)[9]
   b) when they occur in the region of the chiasm they cannot always be distinguished clinically or radiographically from so-called hypothalamic gliomas (p. 695) or gliomas of the third ventricular region
4. brainstem PCAs: 9%. Usually are fibrillary infiltrating type and only a small proportion are pilocytic. May comprise the majority of the prognostically favorable group described as "dorsally exophytic (p. 696)" brainstem gliomas[9,10]
5. spinal cord: 2%. PCAs may also occur here, but little information is available on these. Again, patients tend to be younger than with infiltrating astrocytomas of the spinal cord

Molecular genetics

Detailed molecular genetics are available.[11] For most neurosurgeons, the salient aspects are:

- the most common genetic abnormality in PCAs is in the BRAF gene which activates the MAPK pathway which is involved in nearly all PCAs. This is common in all PCAs, but most prevalent (75%) in cerebellar PCAs
- 15–20% of patients with neurofibromatosis type 1 (NF1) develop PCAs,[12] which are the main CNS tumors associated with NF1. NF1 patients have only 1 NF1 wildtype gene copy. Loss of this copy by a "second hit" (by point mutation, LOH, or DNA hypermethylation[13]) results in overactivation of RAS and MAPK pathway[14]

Histology

PCAs are usually histologically WHO grade 1 (however, a rare anaplastic form in adults has been identified,[15] but a WHO grade 3 variant is not officially recognized).

► **Microscopy.** Low to moderate cellularity with two main cell populations (biphasic), best appreciated in cerebellar PCAs:

1. cells with long thin bipolar processes (resembling hairs—hence *pilo*cytic)[9] with Rosenthal fibers[8] (sausage or corkscrew shaped cytoplasmic eosinophilic inclusion bodies consisting of glial filament aggregates resembling hyaline; stain bright red on Masson trichrome smears)
2. loosely knit tissue comprising stellate astrocytes with microcysts and occasional eosinophilic granular bodies

PCAs easily break through the pia to fill the overlying subarachnoid space. PCAs may also infiltrate into the perivascular spaces. Vascular proliferation is common. Multinucleated giant cells with peripherally located nuclei are common, especially in PCAs of the cerebellum or cerebrum. Mitotic figures may be seen, but are clinically not as ominous as with fibrillary astrocytomas. Areas of necrosis may also be seen. In spite of well-demarcated margins grossly and on MRI, at least 64% of PCAs infiltrate the surrounding parenchyma, especially the white matter[16] (the clinical significance of this is uncertain; one study found no statistically significant decrease in survival[17]).

► **Differentiating from a diffuse or infiltrating astrocytoma.** Pathology alone may not be able to differentiate. This may be especially problematic with small specimens obtained e.g., with stereotactic biopsy. A young age may suggest the diagnosis, and knowledge of the radiographic appearance is often critical (see below).

▶ **Malignant degeneration.** Rare malignant degeneration has been reported, often after many years. Radiation therapy (XRT) had been administered in most cases[18] although this may occur without XRT.[19]

Radiographic evaluation

Preoperative MRI of the entire neuraxis (brain, cervical, thoracic, and lumbar spine) without and with contrast is recommended when possible to evaluate for dissemination through the CSF (rare) and in case it proves to be a different pathology.

On CT or MRI, PCAs are usually well circumscribed, 94% enhance with contrast[16] (unlike most low-grade diffuse astrocytomas), frequently have a cystic component with a mural nodule (especially cerebellar PCAs) (see ▶ Fig. 39.3), and have little or no surrounding edema. The cyst wall may or may not enhance. PCAs involving the optic apparatus are typically fusiform.

Although they may occur anywhere in the CNS, 82% are periventricular.[16] Calcifications are only occasionally present.[16] 4 main imaging patterns of cerebellar or cerebral PCAs are shown in ▶ Table 39.1.

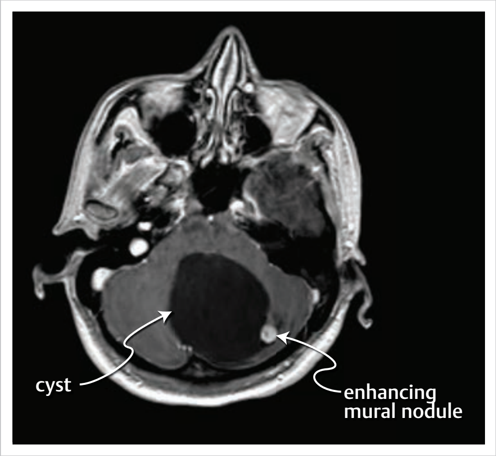


Fig. 39.3 Pilocytic astrocytoma of the posterior fossa.
Note characteristic nonenhancing cyst wall with enhancing mural nodule.
Image: axial T1 MRI with contrast.

Table 39.1 Common imaging characteristics of cerebellar or cerebral PCAs

%	Description	
21	nonenhancing cyst with enhancing mural nodule	over 66% are cystic with enhancing mural nodule
46	enhancing cyst with enhancing mural nodule	
16	mass with nonenhancing central area (necrosis)	
17	solid mass with minimal or no cyst	

Treatment

Treatment of choice is surgical excision of the maximal amount of the tumor that can be removed without producing deficit. In some, invasion of brainstem or involvement of cranial nerves or blood vessels may limit resection.

▶ **Cysts.** In tumors composed of a nodule with a true cyst, excision of the nodule is sufficient; the cyst wall need not be removed (the strength of this statement is based on the fact that the wall has been biopsy proven negative for neoplasm in 3 cases[20] and that patients do very well after excision of the nodule alone). In tumors with a so-called “false cyst” where the cyst wall is thick and enhances (on CT or MRI), this portion must also be removed.

▶ **XRT & chemotherapy.** Because of the high 5- and 10-year survival rates together with the high complication rate of radiation therapy over this time interval—see Radiation injury and necrosis (p. 1899)—and the fact that many incompletely resected tumors enlarge minimally if at all over periods of 5, 10, or even 20 years, it is recommended to *not* radiate these patients post-op. Rather, they should be followed with serial CT or MRI and be re-operated if there is recurrence.[21] Radiation therapy is indicated for nonresectable recurrence (i.e., reoperation is preferred if possible) or for recurrence with malignant histology. Chemotherapy is preferable to XRT in younger patients.[22]

Prognosis

The natural history of these tumors is slow growth. Survival rates at 5 and 10 years are 95% after surgical resection alone.

Tumor recurrence is relatively common, and although it has been said that they generally occur within ≈ 3 yrs of surgery,[23] this is controversial, and very late recurrences are documented,[21] violating Collins' law (which says that a tumor may be considered cured if it does not recur within a time period equal to the patient's age at diagnosis + 9 months). Also, some tumors excised partially fail to show further growth, representing a form of cure (long-term progression free survival).

About 20% of cerebellar PCAs develop hydrocephalus, requiring treatment following surgery.[24] So-called "drop metastases" occur rarely with PCAs.

Pilocytic astrocytoma (PCA) of the cerebellum

General information

Key concepts

- often cystic, half of these have mural nodule
- usually presents during the second decade of life (ages 10–20 yrs)
- also, see Key concepts for pilocytic astrocytomas in general (p. 689)

An informal subtype of pilocytic astrocytoma (PCA) (p. 689). Formerly referred to by the nonspecific and confusing term cystic cerebellar astrocytoma. One of the more common pediatric brain tumors (≈ 15% of primary brain tumors in patients < 19 years[7]), comprising 27–40% of pediatric p-fossa tumors.[25 (p 367–74),26 (p 3032)] They may also occur in adults, where the mean age is lower and the post-operative survival is longer than for diffuse astrocytomas.[27]

Presentation

Signs and symptoms of cerebellar PCAs are usually those of any p-fossa mass, i.e., those of hydrocephalus (headache, nausea/vomiting…) or cerebellar dysfunction (ataxia, cranial nerve deficits) (see Posterior fossa (infratentorial) tumors (p. 624)). Optic pathway gliomas typically present with loss of vision.

Imaging

"Classic" MRI finding: posterior fossa cyst with an enhancing mural nodule (see ▶ Fig. 39.3). The cyst wall sometimes enhances, usually as a thin rim (biopsy negative for neoplasm, enhancement may be reactive[20]).

Pathology

The classic "juvenile pilocytic astrocytoma" of the cerebellum is a distinctive entity with its macroscopic cystic architecture and microscopic spongy appearance.[8] For other microscopic findings, see PCAs in general, above.

These tumors may be solid, but are more often cystic (hence the older term "cystic cerebellar astrocytoma") with a mural nodule. They tend to be large at the time of diagnosis (cystic tumors: 4–5.6 cm diameter; solid tumors: 2–4.8 cm diameter). Cysts contain highly proteinaceous fluid (averaging ≈ 4 Hounsfield units higher density than CSF on CT[28]).

Treatment guidelines

For cystic cerebellar PCAs, excision of the nodule without removing the cyst wall is sufficient. See treatment of pilocytic astrocytomas in general (p. 692).

Also, see Posterior fossa (infratentorial) tumors (p. 624) for guidelines regarding hydrocephalus, etc.

Because of the high frequency of BRAF abnormalities, research is ongoing to evaluate the efficacy of BRAF and/or MEK inhibitors.[29]

Optic pathway glioma (OPG)

General information

Accounts for ≈ 2% of gliomas in adults, and 7% in children. The incidence is higher (≈ 25%) in neurofibromatosis type 1 (NF1) (p. 637). OPG may occur anywhere along the optic pathway from the optic disc to the occipital cortex.

OPGs may arise in any of the following patterns:

1. one optic nerve (without chiasmal involvement): > 25% of OPGs are confined to the optic disc and nerve[30]
2. optic chiasm: 40-70% of OPGs.[30] Less commonly involved in patients with NF1 than in sporadic cases. Aggressive. 33-60% also invade the hypothalamus or third ventricle
3. multicentric in both optic nerves sparing the chiasm: seen almost exclusively in NF1
4. may occur in conjunction with, or be part of, a hypothalamic glioma (see below)

Pathology

Most OPGs are pilocytic astrocytomas (PCA) and are composed of low-grade (pilocytic) astrocytes. Rarely, a malignant chiasmal glioma occurs.

Presentation

Many OPGs remain asymptomatic.

Painless proptosis is an early sign in lesions involving one optic nerve. Chiasmal lesions produce variable and nonspecific visual defects (usually monocular) without proptosis. Large chiasmal tumors may cause hypothalamic and pituitary dysfunction (see diencephalic syndrome below), and may produce hydrocephalus by obstruction at the foramen of Monro. Gliosis of the optic nerve head may be seen on fundoscopy.

Evaluation

Plain X-rays: not usually helpful. The classic skull X-ray findings are enlargement of the optic canals and a "J"-shaped sella turcica.

CT/MRI: CT scan can readily demonstrate structures within the orbit. In addition to that, MRI also easily demonstrates chiasmal or hypothalamic involvement. On CT or MRI, involvement of the optic nerve produces fusiform enlargement of the nerve usually extending > 1 cm in length. Optic pathway gliomas in patients with NF1 are typically isolated to the optic nerve, whereas those not associated with NF1 usually involve the optic chiasm, may extend outside the optic apparatus, and are frequently cystic. Enhancement is usually only mild to moderate.

Biopsy is not needed in cases with characteristic findings.

Treatment

Tumor involving a single optic nerve, sparing the chiasm, producing proptosis and visual loss should be treated with a transcranial approach with excision of the nerve from the globe all the way back to the chiasm (a transorbital [Kronlein] approach is not appropriate since tumor may be left in the nerve stump). In addition to the anticipated blindness in the involved eye, this may produce a junctional scotoma (p. 875).

Chiasmal tumors are generally not treated surgically except for biopsy (especially when it is difficult to distinguish an optic nerve glioma from a hypothalamic glioma), CSF shunting, or to remove the rare exophytic component to try and improve vision.

► **Adjuvant therapy.** Chemotherapy[22] (preferred over XRT in younger patients) or XRT. Indications:

1. chiasmal tumors
2. multicentric tumors
3. post-op if tumor is found in the chiasmal stump end of the resected nerve
4. malignant tumor (rare)

Typical XRT treatment planning: 45 Gy in 25 fractions of 1.8 Gy.

Hypothalamic glioma

General information

Pilocytic astrocytomas of the hypothalamus and third ventricular region occur primarily in children. Radiographically, the lesion may have an intraventricular appearance. Many of these tumors have some chiasmal involvement and the distinction from optic nerve glioma cannot be made (see above).

Presentation

Possible presentations include:

- "**diencephalic syndrome**": a rare syndrome seen in peds, usually caused by an infiltrating glioma of the anterior hypothalamus. Classically:
  a) cachexia (loss of subcutaneous fat)/failure to thrive, failure to gain weight
  b) hyperactivity/over-alertness
  c) an almost euphoric affect (in stark contrast to their gaunt appearance)
- endocrine disturbance
  a) hypoglycemia
  b) diabetes insipidus with attendant hypernatremia
  c) precocious puberty
- symptoms related to hydrocephalus
  a) macrocephaly
  b) headache
  c) nausea/vomiting

Treatment

When complete resection is not possible, adjuvant therapy may be needed as outlined under optic gliomas (above).

Brainstem glioma

General information

Key concepts

- not a homogeneous group. MRI can differentiate malignant from benign lesions
- trend: lower grade tumors tend to occur in the upper brainstem, and higher grade tumors in the lower brainstem/medulla
- usually presents with multiple cranial nerve palsies and long tract findings
- most are malignant, have poor prognosis, and are not surgical candidates
- role of surgery primarily limited to dorsally exophytic lesions and shunting

Brainstem gliomas (BSG) tend to occur during childhood and adolescence (77% are < 20 yrs old, they comprise 1% of adult tumors[31]). BSG are one of the 3 most common brain tumors in pediatrics—see Pediatric brain tumors (p. 621)—comprising ≈ 10–20% of pediatric CNS tumors.[10]

Presentation

See reference.[32]

Upper brainstem tumors tend to present with cerebellar findings and hydrocephalus, whereas lower brainstem tumors tend to present with multiple lower cranial nerve deficits and long tract findings. Due to their invasive nature, signs and symptoms usually do not occur until the tumor is fairly extensive in size.

Signs and symptoms:

1. gait disturbance
2. headache (p. 623)
3. nausea/vomiting
4. cranial nerve deficits: diplopia, facial asymmetry
5. distal motor weakness in 30%
6. papilledema in 50%

7. hydrocephalus in 60%, usually due to aqueductal obstruction (often late, except with periaqueductal tumors, e.g., below)
8. failure to thrive (especially in age ≤ 2 yrs)

Pathology

BSG is a heterogeneous group. There may be a tendency towards lower grade tumors in the upper brainstem (76% were low-grade) versus the lower brainstem (100% of the glioblastomas were in the medulla).[33] A cystic component is seen rarely. Calcifications are also rare. 4 growth patterns that can be identified by MRI[34] that may correlate with prognosis[35]:

1. diffuse: all are malignant (most are anaplastic astrocytomas, the rest are glioblastomas). On MRI these tumors extend into the adjacent region in vertical axis (e.g., medullary tumors extend into pons and/or cervical cord) with very little growth towards obex, remaining intra-axial. Diffuse midline glioma, H3 K27M-mutant (p. 683) is a specific tumor seen mostly in pediatrics (but also uncommonly in adults)
2. cervicomedullary: most (72%) are low-grade astrocytomas. The rostral extent of these tumors is limited to the spinomedullary junction. Most bulge into the obex of the 4th ventricle (some may have an actual exophytic component)
3. focal: extent limited to medulla (does not extend up into pons nor down into spinal cord). Most (66%) are low-grade astrocytomas
4. dorsally exophytic: may be an extension of "focal" tumors (see above). Many of these may actually be low grade gliomas including:
    a) pilocytic astrocytomas (p. 689)
    b) gangliogliomas (p. 706): very rare. Compared to other BSGs, these patients tend to be slightly older and the medulla is involved more frequently[36]

Evaluation

MRI

The diagnostic test of choice. MRI evaluates status of ventricles, gives optimal assessment of tumor (CT is poor in the posterior fossa) and detects exophytic component. See ▶ Fig. 38.6. T1WI: almost all are hypointense, homogeneous (excluding cysts). T2WI: increased signal, homogeneous (excluding cysts). Gadolinium enhancement is highly variable.[34]

CT

Most do not enhance on CT, except possibly an exophytic component. If there is marked enhancement, consider other diagnoses (e.g., high-grade vermian astrocytoma).

Treatment

Surgery

Biopsy: biopsy for diffuse non-exophytic infiltrating tumors was discouraged[37]; however, changing trends are leaning towards biopsy even when the MRI shows a diffuse infiltrating brainstem lesion (to look for H3 K27 M mutation (p. 683)).[38]

Treatment is usually non-surgical. Exceptions where surgery may be indicated:

1. tumors with a dorsally exophytic component[10]: see below; these may protrude into 4th ventricle or CP angle, tend to enhance with IV contrast, tend to be lower grade
2. some success has been achieved with non-exophytic tumors that are *not* malignant astrocytomas (surgery in malignant astrocytomas is without benefit)[35] (detailed follow-up is lacking)
3. shunting for hydrocephalus

Stereotactic biopsy can be transfrontal, of for lesions entering the cerebellar peduncle a transcerebellar approach with the patient positioned on their side mahy be used.

Dorsally exophytic tumors

These tumors are generally histologically benign (e.g., gangliogliomas) and are amenable to radical subtotal resection. Prolonged survival is possible, with a low incidence of disease progression at short-term follow-up.[10]

Surgical goals in exophytic tumors include:

1. enhanced survival by subtotal removal of exophytic component[39]: broad attachment to the floor of 4th ventricle is typical and usually precludes complete excision (although some "safe entry" zones have been described[40]). An ultrasonic aspirator facilitates debulking
2. establishing diagnosis: radiographic differentiation of exophytic brainstem glioma tumors from other lesions (e.g., medulloblastoma, ependymoma, and dermoids) may be difficult

3. tumors that demonstrate recurrent growth after resection remained histologically benign and were amenable to re-resection[10]

Complications of surgery generally consisted of exacerbation of preoperative symptoms (ataxia, cranial nerve palsies…) which usually resolved with time.

Medical

No proven chemotherapeutic regimen. Steroids are usually administered. In pediatrics, there is some indication of response to Temodar® (temozolomide) (p. 627).

Radiation

Traditionally given as 45–55 Gy over a six week period, five days per week. When combined with steroids, symptomatic improvement occurs in 80% of patients.

Possible improved survival with so called "hyperfractionation" where multiple smaller doses per day are used.

Prognosis

Most children with malignant BSG will die within 6–12 months of diagnosis. XRT may not prolong survival in patients with grade 3 or 4 tumors. A subgroup of children have a more slowly growing tumor and may have up to 50% five-year survival. Dorsally exophytic tumors composed of pilocytic astrocytomas may have a better prognosis.

Tectal gliomas

General information

A topically defined diagnosis generally consisting of low-grade astrocytomas. Considered a benign subgroup of brainstem glioma. Because of location, tends to present with hydrocephalus. Was dramatically referred to as "the smallest tumor in the body that can lead to the death of the patient."[41] Focal neurologic findings are rare—diplopia, visual field deficits, nystagmus, Parinaud's syndrome (p. 101), ataxia, seizures…—and are often reversible after the hydrocephalus is corrected.

Epidemiology

Comprises ≈ 6% of surgically treated pediatric brain tumors.[42] Presents primarily in childhood. Median age of patients becoming symptomatic = 6–14 years.[42]

Pathology

Since many of these are not biopsied, meaningful statistical analysis is not possible. Pathologies identified include: WHO grade 2 diffuse astrocytoma, pilocytic astrocytomas, WHO grade 2 ependymoma, anaplastic astrocytoma, oligodendroglioma, and oligoastrocytoma.

Radiographic evaluation

CT scan detects hydrocephalus, but may miss the tumor in ≈ 50%.[43] Calcification on CT has been described in 9–25%.[43,44]

MRI is the study of choice for diagnosis and follow-up. Typically appears as a mass projecting dorsally from the quadrigeminal plate. Isointense on T1WI, iso- or hyperintense on T2WI.[42,45] Enhancement with gadolinium occurs in 18% and is of uncertain prognostic significance.

Treatment

General information

Due to the indolent course, open surgery is not recommended. Options include:

1. VP shunt: the standard treatment for years. Long-term results are good with a functioning shunt
2. endoscopic third ventriculostomy: may avoid the need for a shunt. Endoscopic biopsy[46] may be done at the same time through the same burr hole if it is technically feasible (requires a dilated foramen of Monro, which is often present). Long-term results unknown
3. endoscopic aqueductoplasty (with or without stenting): an option for some. Long-term results unknown

Stereotactic radiosurgery: May be offered for tumor progression (criteria are not defined: radiographic progression may not be associated with clinical deterioration[45]). Dosing should be limited to ≤ 14 Gray at the 50–70% isodose line to avoid radiation-induced side effects.[47]

Prognosis

Tumor progression: described in 15–25%.

Follow-up: no accepted guidelines. Serial neurologic exams and MRIs every 6–12 months has been suggested.[42]

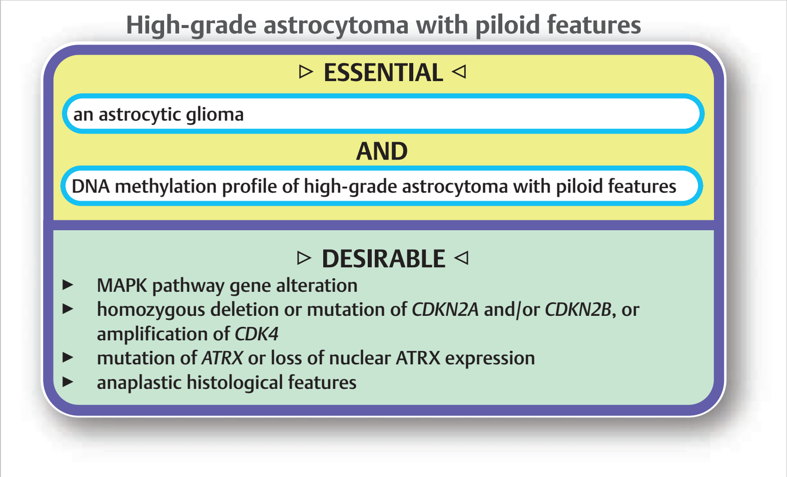
39.2.2 High-grade astrocytoma with piloid features (HGAP) (WHO grade N/A)

General information

A rare astrocytoma that often shows high-grade piloid and/or glioblastoma-like features, possessing a distinct DNA methylation profile. These tumors may arise de novo, but they can also develop from lower grade astrocytomas, including pilocytic astrocytoma. Prognostic information is limited, with a 5-year OS of 50%.[48]

Diagnostic criteria for high-grade astrocytoma with piloid features

Diagnostic criteria for high-grade astrocytoma with piloid features are shown in ▶ Fig. 39.4.[1]



High-grade astrocytoma with piloid features

▷ ESSENTIAL ◁

an astrocytic glioma

AND

DNA methylation profile of high-grade astrocytoma with piloid features

▷ DESIRABLE ◁

- ▶ MAPK pathway gene alteration
- ▶ homozygous deletion or mutation of *CDKN2A* and/or *CDKN2B*, or amplification of *CDK4*
- ▶ mutation of *ATRX* or loss of nuclear ATRX expression
- ▶ anaplastic histological features

Fig. 39.4 Diagnostic criteria for high-grade astrocytoma with piloid features. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

39.2.3 Pleomorphic xanthoastrocytoma (PXA) (WHO grade 2 or 3)

General information

Key concepts

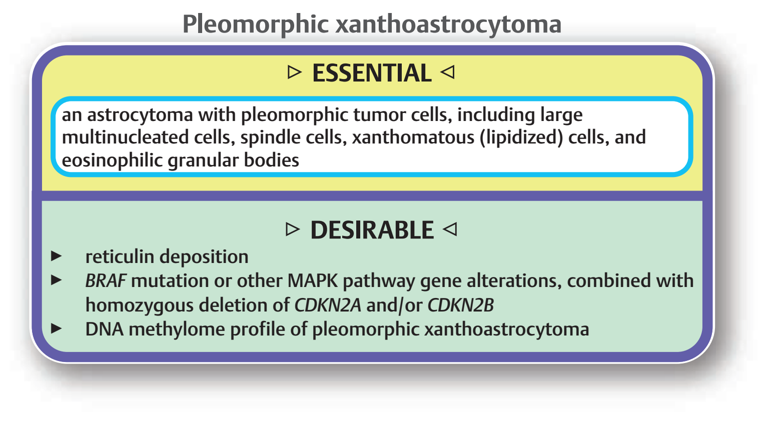
- a glioma (usually WHO grade 2), possibly from subpial astrocytes → superficial location involving the leptomeninges in > 67%
- 98% supratentorial, most common in children or young adults
- mural nodule with cystic component in 25%
- histology: large pleomorphic cells (xanthomatous [lipid-laden] cells, fibrillary and giant multinucleated astrocytes) often containing eosinophilic granular bodies and reticulin deposition
- characteristically with MAPK pathway gene alterations

- usually circumscribed, occasionally invasive
- WHO grade 2 (if ≥ 5 mitoses per HPF it qualifies as anaplastic, WHO grade 3)
- treatment: maximal safe resection

A low-grade glioma thought to arise from subpial astrocytes, which may explain their superficial location and abundance of reticulin fibers. Over 90% are supratentorial. Predilection for temporal lobes (50%), followed by parietal, occipital & frontal lobes. Most have a cystic component (may be multiloculated, but > 90% have a large, single cyst).

Diagnostic criteria for pleomorphic xanthoastrocytoma

Diagnostic criteria for pleomorphic xanthoastrocytoma are shown in ▶ Fig. 39.5.[1]



Pleomorphic xanthoastrocytoma

▷ ESSENTIAL ◁

an astrocytoma with pleomorphic tumor cells, including large multinucleated cells, spindle cells, xanthomatous (lipidized) cells, and eosinophilic granular bodies

▷ DESIRABLE ◁

- reticulin deposition
- *BRAF* mutation or other MAPK pathway gene alterations, combined with homozygous deletion of *CDKN2A* and/or *CDKN2B*
- DNA methylome profile of pleomorphic xanthoastrocytoma

Fig. 39.5 Diagnostic criteria for pleomorphic xanthoastrocytoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Epidemiology

≈ 1% of astrocytomas. Usually occurs in children or young adults (most are < 18 years of age). No gender difference. High prevalence of MAPK pathway alterations in PXA may explain the association with NF1.

Clinical

Usual presentation: seizures. May also produce focal deficit or increased ICP.

Differential diagnosis

1. imaging: meningioma is also superficial with dural tail. PXA may also resemble a low grade diffuse astrocytoma
2. pathology: may be confused with anaplastic astrocytoma

Histology

A compact, superficial tumor, usually circumscribed, occasionally infiltrates cortex. Marked cellular pleomorphism (fibrillary and giant multinucleated astrocytes, large xanthomatous (lipid laden) may cause these tumors to be mistaken for anaplastic astrocytoma. Cells stain for GFAP, bespeaking glial origin. Abundant eosinophilic granular bodies, reticulin and frequent perivascular chronic inflammatory cells. The reticulin fibers surround two cell types:

1. spindle cells: fusiform cell shape with elongated nuclei
2. pleomorphic cells: round cells with heterochromic, pleomorphic nuclei that may be mononucleated or multinucleated. Variable intracellular lipid content

Grading

Most PXAs are WHO grade 2 with an MIB typically < 1%. A high mitotic index (≥ 5 mitoses per 10 HPF) qualifies as WHO grade 3.[49] Necrosis is common in grade 3 PXAs, but the significance of necrosis when encountered alone is not determined.

Dedifferentiation

PXAs have a tendency to recur and undergo anaplastic change.[50] There have also been several reported cases of malignant transformation to anaplastic astrocytoma or glioblastoma.[51]

Molecular genetics

Almost all PXAs demonstrate abnormal activation of MAPK pathway due to genetic alterations. The most common alteration is in *BRAF* V600E, and when seen in the absence of IDH mutation is strongly supportive of the diagnosis.

Other MAPK pathway gene alterations include homozygous *CDKN2A* and/or *CDKN2B*deletion.

Imaging

The cyst, when present, may partially enhance on CT or MRI. A mural nodule is present in 25%. May have “dural tail” (67% show leptomeningeal involvement, 13% show involvement of all 3 meningeal layers). Peritumoral edema may be mild to moderate, calcifications are rare.[52]

CT: solid portion of tumor is ill-defined and may be isodense to gray matter.

MRI: T1WI: hypointense cystic component with ill-defined isointense solid component that strongly enhances with gadolinium. T2WI: hyperintense cystic component with ill-defined isointense solid component.

Since PXAs tend to disseminate when they progress, spine MRI is recommended at the time of clinical progression.

Treatment

1. surgery: primary treatment
    a) gross total resection if it can be accomplished without unacceptable neurologic deficit, otherwise subtotal resection
    b) extent of resection: most strongly associated with recurrence free survival[53]
    c) incomplete resections should be followed since these tumors may grow very slowly over many years before retreatment is necessary, and repeat excision should be considered
2. radiation therapy: controversial
    a) literature suggests either no difference in overall survival or possibly a trend toward prolonged survival[54]
    b) considered with: residual disease, high mitotic index, or necrosis
3. chemotherapy: role not defined

Prognosis

PXAs frequently recur and malignant progression is more common than other WHO CNS5 grade 1 or 2 gliomas in young patients.

Grade 3 PXAs fare much worse than grade 2, with 5-year recurrence-free survival of 71% for grade 2 PXAs, and 49% for grade 3 ($P = .0003$).[55] OS is 54 months for grade 2 vs. 33 for grade 3.[56]

Extent of resection, mitotic index, and necrosis appear to be the best predictors of outcome.[52,53]

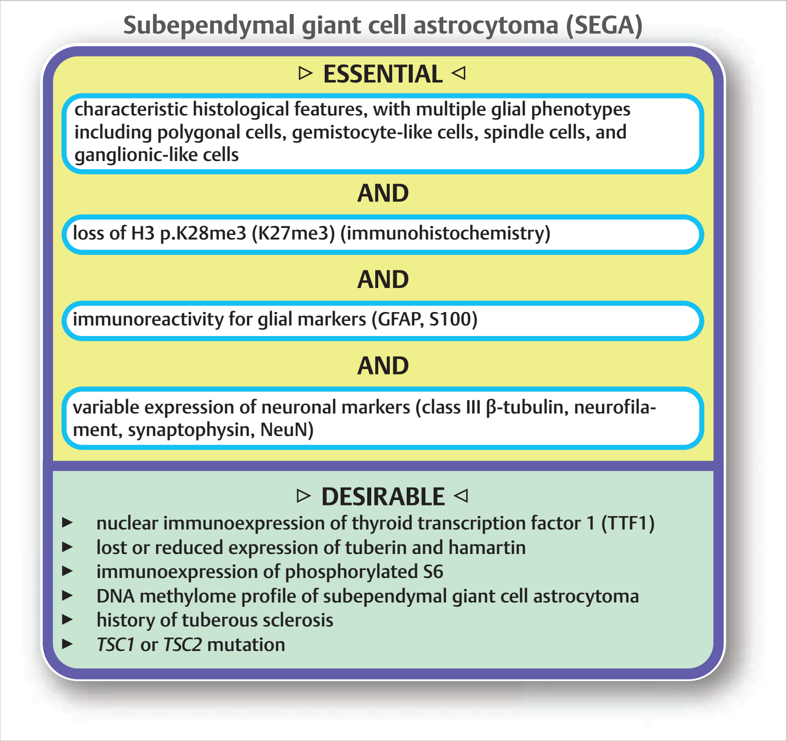
39.2.4 Subependymal giant cell astrocytoma (SEGA) (WHO grade 1)

General information

A circumscribed and often calcified WHO grade 1 tumor having a strong association with tuberous sclerosis (p. 644) (it is unclear if SEGAs develop in the absence of this condition).

Diagnostic criteria for subependymal giant cell astrocytoma

Diagnostic criteria for subependymal giant cell astrocytoma are shown in ▶ Fig. 39.6.[1]



Subependymal giant cell astrocytoma (SEGA)

▷ ESSENTIAL ◁

characteristic histological features, with multiple glial phenotypes including polygonal cells, gemistocyte-like cells, spindle cells, and ganglionic-like cells

AND

loss of H3 p.K28me3 (K27me3) (immunohistochemistry)

AND

immunoreactivity for glial markers (GFAP, S100)

AND

variable expression of neuronal markers (class III β-tubulin, neurofilament, synaptophysin, NeuN)

▷ DESIRABLE ◁

- nuclear immunoexpression of thyroid transcription factor 1 (TTF1)
- lost or reduced expression of tuberin and hamartin
- immunoexpression of phosphorylated S6
- DNA methylome profile of subependymal giant cell astrocytoma
- history of tuberous sclerosis
- *TSC1* or *TSC2* mutation

Fig. 39.6 Diagnostic criteria for subependymal giant cell astrocytoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Epidemiology & genetics

Incidence in patients with tuberous sclerosis is 5-15%. SEGAs rarely occur de novo after age ≈ 25 years.

SEGAs typically possess biallelic inactivation of *TSC1* (15%) or *TSC2* (56%) with the second hit being deletion or loss of heterozygosity. Deficient tuberin and hamartin epression are observed with these mutations.

Location

Arise from the lateral walls of the lateral ventricles next to the foramen of Monro. Rarely found in the third ventricle.

Histology

A wide variety of phenotypes occur. Large, plump cells resembling gemistocytic astrocytes are common, arrayed in fascicles, sheets and nests. Polygonal cells with ample cytoplasm may be seen. Areas of necrosis and mitotic figures may be seen, but are not associated with the typical malignant aggressiveness that these features usually denote.[57] Mean Ki-67 (p. 632) is 3%.

Prognosis

Gross total resection is associated with a favorable prognosis. Larger lesions or symptomatic lesions have increased risk of surgical morbidity.[58]

Everolimus may reduce tumor size and progression.[59]

Because of the risk of late recurrence, long-tem follow-up is recommended.

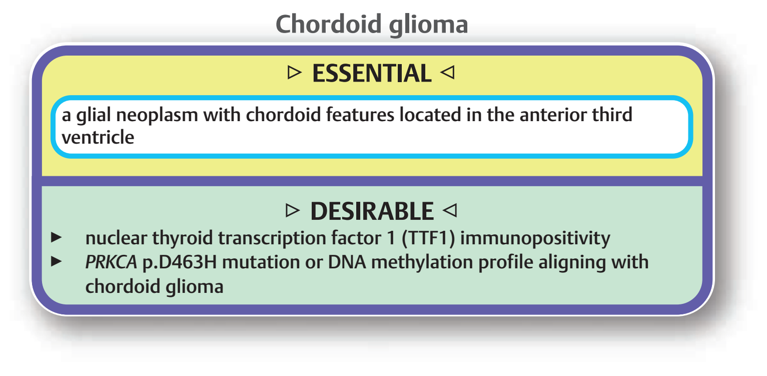
39.2.5 Chordoid glioma (WHO grade 2)

General information

A glioma that occurs in the anterior third ventricle, possibly arising from tanycyte ependymal cells of the organum vasculosum of the lamina terminalis.

Diagnostic criteria for chordoid glioma

Diagnostic criteria for chordoid glioma are shown in ▶ Fig. 39.7.[1]



Chordoid glioma

▷ ESSENTIAL ◁

a glial neoplasm with chordoid features located in the anterior third ventricle

▷ DESIRABLE ◁

- nuclear thyroid transcription factor 1 (TTF1) immunopositivity
- *PRKCA* p.D463H mutation or DNA methylation profile aligning with chordoid glioma

Fig. 39.7 Diagnostic criteria for chordoid glioma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Epidemiology & genetics

Comprise < 0.1% of primary brain tumors, typically occurring in adults. Female preponderance of 2:1.[60]

Presentation

- obstructive hydrocephalus: with typical symptoms of H/A, N/V, obtundation
- endocrine disturbance (hypothyroidism, amenorrhea, diabetes insipidus) from compression of the hypothalamus visual field deficit from compression of the chiasm
- psychiatric symptoms: personality changes, memory disturbance…

Imaging

MRI shows a well-circumscribed mass isotintense to brain on T1 images with avid enhancement, located in the anterior third ventricle (large tumors may occupy the entire third ventricle).

Histology

Typically comprised of clusters and cords of epitheliod cells embedded in a mucinous stroma. GFAP immunostaining is common. Mitotic activity is absent in most.

Treatment

Maximal safe resection is the primary treatment modality. Attachment to the wall of the 3rd ventricle (hypothalamus) may prevent total removal. Surgical risks include insufficiency of hypothalamic hormones, including diabetes insipidus. Post-op adjuvane therapy with XRT is of uncertain benefit.

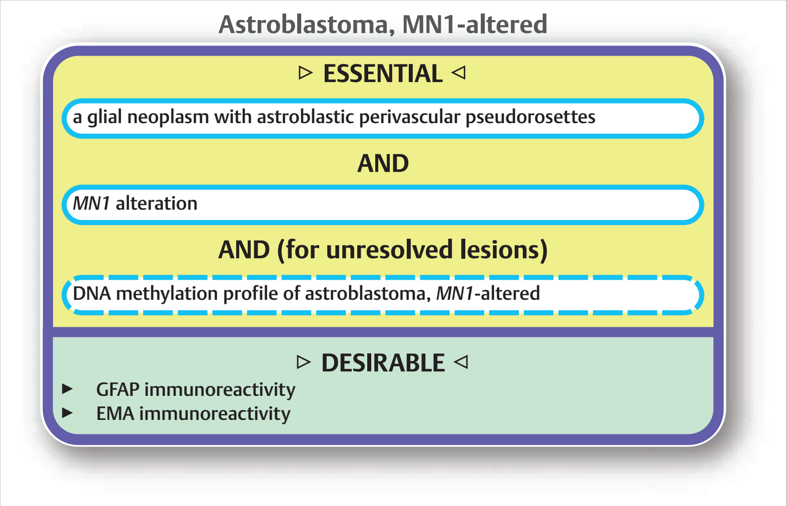
39.2.6 Astroblastoma, MN1-altered (WHO grade 1)

General information

A circumscribed glial tumor with MN1 alteration.

Diagnostic criteria for astroblastoma, MN1-altered

Diagnostic criteria for astroblastoma, MN1-altered are shown in ▶ Fig. 39.8.[1]



Astroblastoma, MN1-altered

▷ ESSENTIAL ◁

a glial neoplasm with astroblastic perivascular pseudorosettes

AND

***MN1* alteration**

AND (for unresolved lesions)

DNA methylation profile of astroblastoma, *MN1*-altered

▷ DESIRABLE ◁

- **GFAP immunoreactivity**
- **EMA immunoreactivity**

Fig. 39.8 Diagnostic criteria for astroblastoma, MN1-altered. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Epidemiology & genetics

Occurs almost exclusively in females.[61] Median age of presentation is 15 years (range: 3 months to 40 years).

Location

Primarily in the cerebral hemispheres, typically in the frontal or parietal lobes, but also may occur in the occipital or temporal lobes. Has also been described in the brainstem, intraventricular compartment and spinal cord.

Imaging

Solid or cystic mass that is iso- to hypo-intense to brain on T1 MRI, hyperintense on T2, and heterogeneous enhancement.

Histology

Hallmark is the astroblastic pseudorosette (tumor cells arranged in a radial pattern around blood vessels).

Treatment and prognosis

Maximal safe resection is associated with longer OS.[62] XRT and chemotherapy areoptions when surgery is not feasible.

5- and 10-year survival rates are 90% and 50% respectively.

40 Glioneuronal and Neuronal Tumors

40.1 Glioneuronal tumors

40.1.1 Ganglioglioma (WHO grade 1)

General information

Key concepts

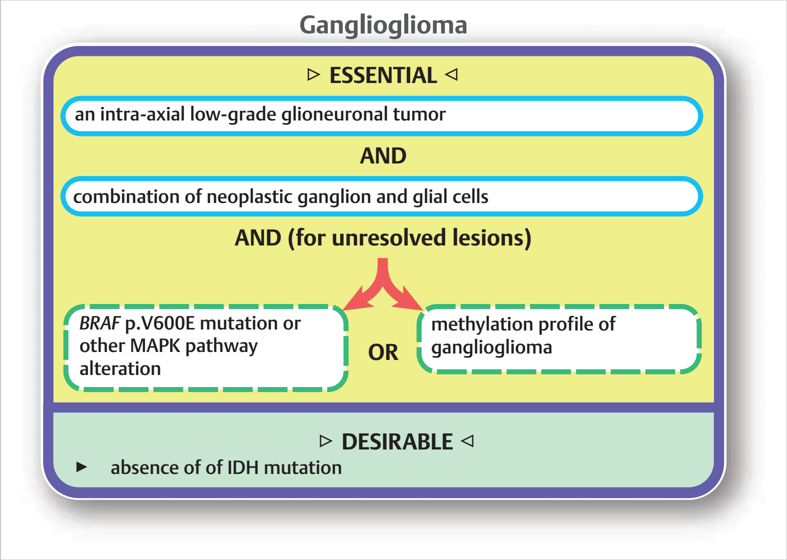
- a well-circumscribed tumor composed of two cell types: ganglion cells (neurons) and glial cells
- extremely rare (< 2% of intracranial neoplasms)
- seen primarily in the first 3 decades of life
- characterized by slow growth and a tendency to calcify

A very slow-growing well-differentiated (WHO grade 1) glioneuronal tumor that primarily affects children and young adults. Composed of two types of cells, dysplastic ganglion cells (neurons) in conjunction with neoplastic glial cells (usually astrocytic in any phase of differentiation).[1] The term "ganglioglioma" was introduced in 1930 by Courville.[2]

An anaplastic ganglioglioma may exist in which the glial component exhibits anaplasia in the form of pronounced mitotic activity with a high Ki-67 proliferation index, necrosis and microvascular proliferation, however, most studies have lacked molecular analysis to exclude other tumor types, and refined data is therefore needed.

Diagnostic criteria for ganglioglioma

Diagnostic criteria for ganglioglioma are shown in ▶ Fig. 40.1.[3]



Ganglioglioma
▷ ESSENTIAL ◁
an intra-axial low-grade glioneuronal tumor
AND
combination of neoplastic ganglion and glial cells
AND (for unresolved lesions)
BRAF p.V600E mutation or other MAPK pathway alteration
OR
methylation profile of ganglioglioma
▷ DESIRABLE ◁
▶ absence of of IDH mutation

Fig. 40.1 Diagnostic criteria for ganglioglioma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Epidemiology

Incidence: Typically quoted[4] as 0.3–0.6%. One series[5] found gangliogliomas in 1.3% of all brain tumors (including mets), or 3% of primary brain tumors.

Demographics: Occurs primarily in children and young adults (peak age of occurrence: 11 yrs). Considering only children and young adults, incidence ranges from 1.2–7.6% of brain tumors.[4]

Location

May occur in various parts of the nervous system (cerebral hemispheres, spinal cord, brainstem, cerebellum, pineal region, thalamus, intrasellar, optic nerve, and peripheral nerve have been reported[4]). Most occur above the tentorium, primarily in the temporal lobe (> 70%) or near the 3rd ventricle, in the hypothalamus or in the frontal lobes.[6] Brainstem gangliogliomas (p. 696) occur rarely.

Histology

Mixture of 2 types of neoplastic cells: neuronal (ganglion) and astrocytic (glial).

Grossly: white matter mass, well-circumscribed, firm, with occasional cystic areas and calcified regions. Most dissect easily from brain, but the solid portion may show an infiltrative tendency.[4]

Microscopically: ganglion cells demonstrate nerve cell differentiation, e.g., Nissl substance and axons or dendrites. Pitfall: differentiating neoplastic neurons from neurons entrapped by an invading astrocytoma may be difficult. Also, neoplastic astrocytes may resemble neurons on light microscopy. 2 of 10 patients had areas of oligodendroglioma. Also seen: necrotic areas, minimal calcification, and Rosenthal bodies.[7]

Radiologic evaluation

Neuroradiologic findings are not specific for this tumor.

CT: all of 10 patients had a low density lesion on non-contrast CT.[5] Tumor calcification are best appreciated on CT and are seen in 30%. Frequently appears cystic on CT, but still may be found to be solid at operation.

MRI: T1WI low to iso-intense with variable enhancement. T2WI hyperintense. Calcifications appear as low signal on both.

CT and MRI: the temporal lobe is favored. Mass effect rare (suggests slow growth). Enhancement varies from none to intense.

Plain skull X-ray: calcification may be noted.

Treatment

Recommendation is maximal safe resection. Close follow-up is recommended, and re-resection should be considered for recurrence. The role of XRT is unknown, and due to the deleterious effects together with the good long-term prognosis, it is not recommended initially but may be considered for recurrence.[8]

Prognosis

These benign tumors have a 97% 7.5-year recurrence-free survival rate.

Prognosis is better with temporal lobe location, gross total excision, and chronic epilepsy.

The correlation between histologic anaplasia and outcome is inconsistent.

The prognosis following subtotal resection of brainstem gangliogliomas is better than for brainstem gliomas as a group.[6]

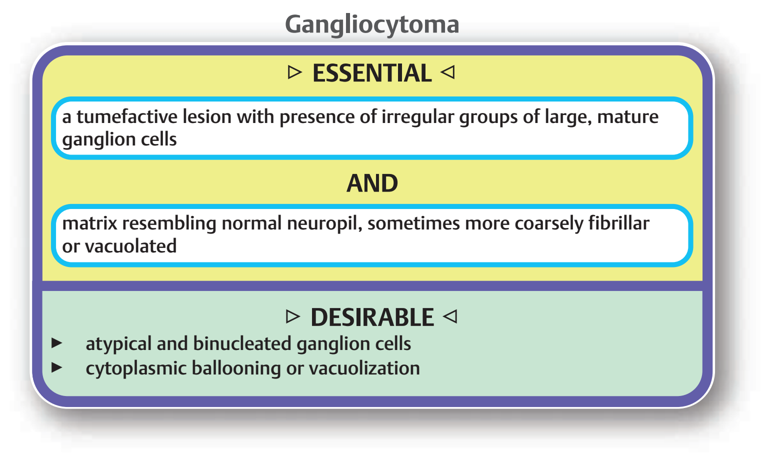
40.1.2 Gangliocytoma (WHO grade 1)

General information

A rare, slow-growing well-differentiated (WHO grade 1) tumor that primarily affects children, characterized by clusters of neoplastic ganglion cells, frequently with dysplastic features.

Diagnostic criteria for gangliocytoma

Diagnostic criteria for gangliocytoma are shown in ▶ Fig. 40.2.[3]



Gangliocytoma

▷ **ESSENTIAL** ◁

a tumefactive lesion with presence of irregular groups of large, mature ganglion cells

AND

matrix resembling normal neuropil, sometimes more coarsely fibrillar or vacuolated

▷ **DESIRABLE** ◁

- atypical and binucleated ganglion cells
- cytoplasmic ballooning or vacuolization

Fig. 40.2 Diagnostic criteria for gangliocytoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Location

As with ganglioglioma, gangliocytomas can occur anywhere in the CNS. Most occur above the tentorium, primarily in the temporal lobe (> 70%) or near the 3rd ventricle, in the hypothalamus or in the frontal lobes.[6] They have been described in the pituitary.

Prognosis

Gangliocytomas are benign tumors with generallly good prognosis. No specific prognostic inidcators have been identified.

40.1.3 Desmoplastic infantile ganglioglioma (DIG) & desmoplastic infantile astrocytoma (DIA) (WHO grade 1)

General information

DIA & DIG are benign (WHO grade 1) glioneural tumor with a neuroepithelial population (restricted to either neoplastic astrocytes only (DIA) or to astrocytes with a variably mature neuronal component (DIG)) in a desmoplastic stroma.

DIA & DIG usually occur primarily in the cerebral hemispheres of infants, often as a large cystic lesion, frequently attached to dura. They are driven by MAPK pathway alteration.

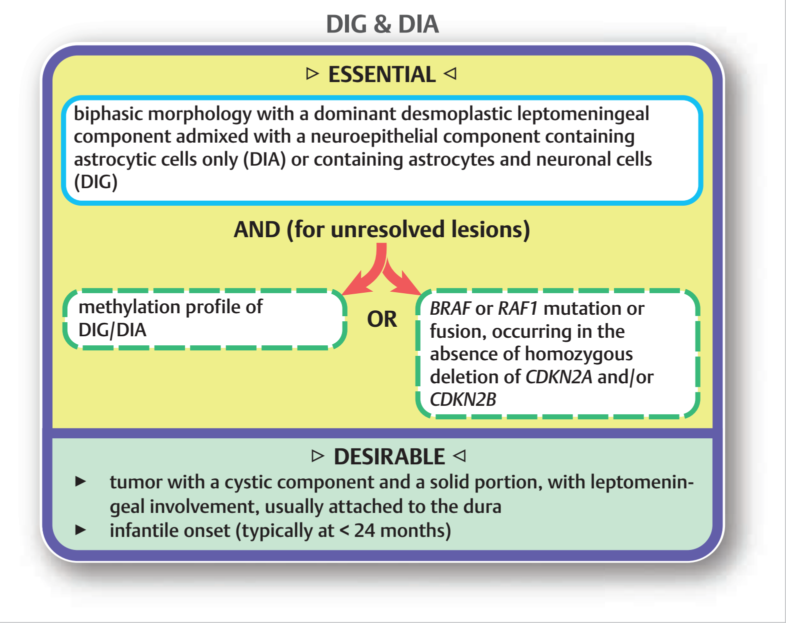
These tumors rarely seed through the CSF.[9]

Diagnostic criteria for desmoplastic infantile ganglioglioma & desmoplastic infantile astrocytoma

Diagnostic criteria for desmoplastic infantile ganglioglioma & desmoplastic infantile astrocytoma are shown in ▶ Fig. 40.3.[3]

Prognosis

Prognosis is usually favorable with gross total resection, with no relapse in 5-15 years of follow-up. They can rarely recur with anaplastic transformation as long as 8-10 years after initial resection, and the reponse to re-resection is promising.[10]



DIG & DIA

▷ **ESSENTIAL** ◁

biphasic morphology with a dominant desmoplastic leptomeningeal component admixed with a neuroepithelial component containing astrocytic cells only (DIA) or containing astrocytes and neuronal cells (DIG)

AND (for unresolved lesions)

methylation profile of DIG/DIA

OR

BRAF or *RAF1* mutation or fusion, occurring in the absence of homozygous deletion of *CDKN2A* and/or *CDKN2B*

▷ **DESIRABLE** ◁

- tumor with a cystic component and a solid portion, with leptomeningeal involvement, usually attached to the dura
- infantile onset (typically at < 24 months)

Fig. 40.3 Diagnostic criteria for desmoplastic infantile ganglioglioma & desmoplastic infantile astrocytoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

40.1.4 Dysembryoplastic neuroepithelial tumor (DNT) (WHO grade 1)

General information

A WHO grade 1 glioneuronal tumor usually cortically based in the temporal lobe of children and young adults, characterized by a multinodular architecture with neuroglial columns, with a pathognomonic glioneuronal element.

Thought to arise embryologically from the secondary germinal layer (which includes subependymal layer, cerebellar external granular layer, hippocampal dentate fascia, and subpial granular layer).

Most DNTs are sporadic, and result from *FGFR1* alterations present in 40-80% of DNTs which upregulate the MAPK and PI3K pathways. *BRAF* p.V600E mutations are found in up to 50% in some studies.

Diagnostic criteria for dysembryoplastic neuroepithelial tumor

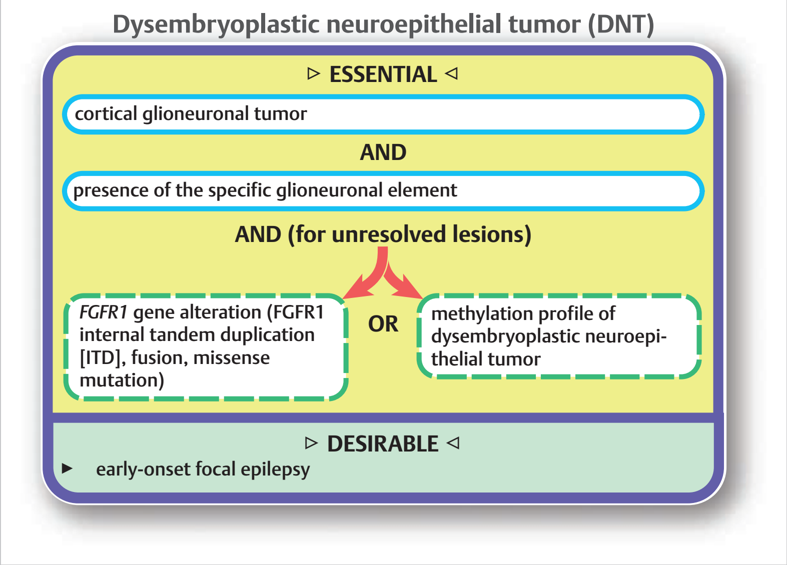
Diagnostic criteria for dysembryoplastic neuroepithelial tumor are shown in ▶ Fig. 40.4.[3]

Epidemiology

Incidence: not accurately known because the diagnosis may be missed. Estimated range: 0.8–5% of all primary brain tumors. Typically occurs in children and young adults. Slight preponderance in males.

Location

DNTs have a predilection for the temporal lobes (67% of cases) and the frontal lobe (16%), with the remainder occurring in any other location within the cerebral cortex.



Dysembryoplastic neuroepithelial tumor (DNT)
▷ ESSENTIAL ◁
cortical glioneuronal tumor

OR
methylation profile of dysembryoplastic neuroepithelial tumor
▷ DESIRABLE ◁
► early-onset focal epilepsy

Fig. 40.4 Diagnostic criteria for dysembryoplastic neuroepithelial tumor. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Histology

Multinodularity at low-power is a key feature with neuroglial columns comprised of bundles of axons aligned perpendicular to the cortical surface. These columns are lined by oligodendriglial like cells incorporated within a mucoid matrix with interspersed neurons.[11] Occasionally difficult to differentiate from oligodendroglioma.

Two distinct forms[12] (do not appear to have different prognoses):

1. simple form: glioneural elements consisting of axon bundles perpendicular to the cortical surface, lined with oligodendroglial-like cells that are S-100 positive and GFAP negative. Normal appearing neurons floating in a pale eosinophilic matrix are scattered between these columns (no resemblance to ganglion cells, unlike gangliogliomas)
2. complex form: glioneural elements as described above in the simple form, with glial nodules scattered throughout. The glial component may mimic a low-grade fibrillary astrocytoma. Foci of cortical dysplasia occur

Clinical

Typically associated with longstanding medically intractable seizures, usually complex partial. Symptoms usually begin before age 20.

Imaging

Cortical lesions that traverse the entire cortical mantle with no surrounding edema and no midline mass effect.

CT: hypodense with distinct margins. Deformity of overlying calvaria is common.

MRI: T1WI: hypointense. T2WI: hyperintense, septations may be seen. If there is enhancement, it is usually nodular.

PET scan: hypometabolic with [18F]-fluorodeoxyglucose. Negative [11C]-methionine uptake (unlike all other gliomas).

Prognosis

Seizure control: usually improves after surgery. Degree of control seems to correlate with completeness of removal. Improvement in seizures correlates inversely with the duration of intractable seizures.

Recurrence/continued growth: recurrence after complete removal, or tumor growth after partial resection is rare. Adjuvant treatment (XRT, chemotherapy…) is of no benefit in these benign tumors. Mitoses or endothelial proliferation, seen on occasion, do not affect outcome. Malignant transformation is very rare.

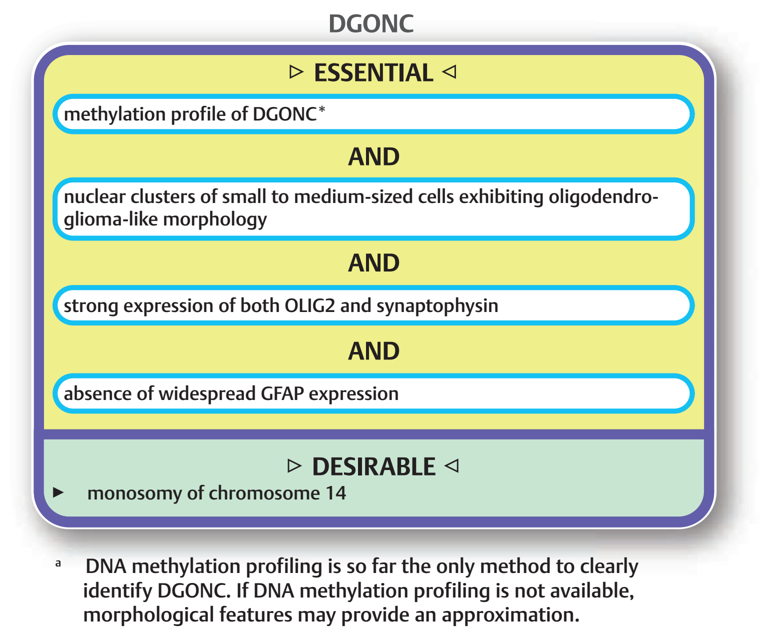
40.1.5 Diffuse glioneuronal tumor with oligodendroglioma-like features and nuclear clusters (DGONC) (WHO grade N/A)

General information

DGONC is a provisional entity for a neuroepithelial tumor with variably differentiated cells, often possessing perinuclear haloes, scattered multinucleated cells and nuclear clusters, having a distinct DNA methylation profile and frequent chromosome 14 monosomy.

Diagnostic criteria for diffuse glioneuronal tumor with oligodendroglioma-like features and nuclear clusters (DGONC)

Diagnostic criteria for DGONC are shown in ▶ Fig. 40.5.[3]



DGONC

▷ ESSENTIAL ◁

methylation profile of DGONC*

AND

nuclear clusters of small to medium-sized cells exhibiting oligodendroglioma-like morphology

AND

strong expression of both OLIG2 and synaptophysin

AND

absence of widespread GFAP expression

▷ DESIRABLE ◁

- monosomy of chromosome 14

[a] DNA methylation profiling is so far the only method to clearly identify DGONC. If DNA methylation profiling is not available, morphological features may provide an approximation.

Fig. 40.5 Diagnostic criteria for DGONC. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Location

In the small number of cases reported, all were supratentorial.[13,14]

Prognosis

Outcome has been report only for 26 cases which showed 81% 5-year PFS, and 89% 5-year OS.[13,14] Treatment data are available only for 3 patients.

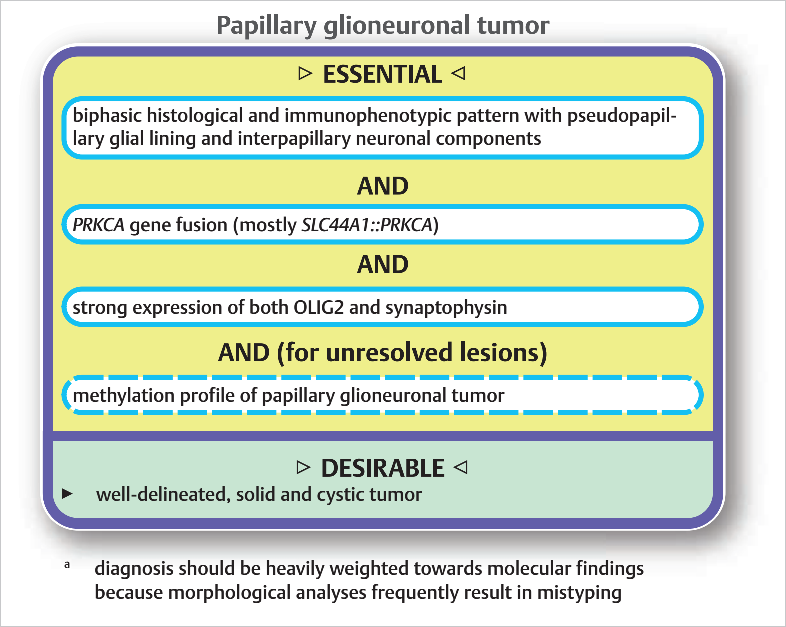
40.1.6 Papillary glioneuronal tumor (PGNT) (WHO grade 1)

General information

A rare glioneuronal tumor of young adults with a biphasic pattern and variable manifestation of pseudopapillary glial structures and interpapillary neuronal components, and possessing *PRKCA* gene fusion (primarily *SLC44A1*::*PRKCA* fusion).

Diagnostic criteria for papillary glioneuronal tumor

Diagnostic criteria for papillary glioneuronal tumor are shown in ▶ Fig. 40.6.[3]



Papillary glioneuronal tumor

▷ ESSENTIAL ◁

biphasic histological and immunophenotypic pattern with pseudopapillary glial lining and interpapillary neuronal components

AND

PRKCA gene fusion (mostly *SLC44A1::PRKCA*)

AND

strong expression of both OLIG2 and synaptophysin

AND (for unresolved lesions)

methylation profile of papillary glioneuronal tumor

▷ DESIRABLE ◁

- well-delineated, solid and cystic tumor

[a] diagnosis should be heavily weighted towards molecular findings because morphological analyses frequently result in mistyping

Fig. 40.6 Diagnostic criteria for papillary glioneuronal tumor. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Location

PGNT are supratentorial, most often in the temporal lobe (28%), frequently in proximity to the lateral ventricle (28%).[15]

Imaging

PGNT appear as well demarcated lesions with solid and cystic components and mild mass effect and edema. Portions may enhance with contrast.

Prognosis

The ability to achieve gross total excision is the primary prognostic factor.

40.1.7 Rosette-forming glioneuronal tumor (RGNT) (WHO grade 1)

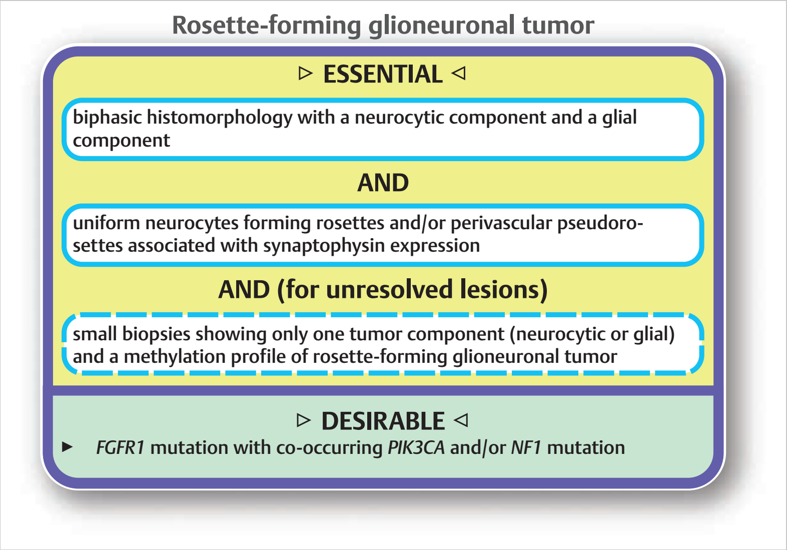
General information

A rare, slow-growing WHO 1 glioneuronal tumor with two histological components: 1) uniform neurocytes forming rosettes and/or perivascular pseudorosettes, and 2) glial component with piloid and oligodendrogliocyte-like cells resembling a pilocytic astrocytoma.

Although WHO grade 1, they occasionally develop satellitle lesions, leptomeningeal involvement or "drop mets" (dissemination of tumor through the CSF to dependent areas, e.g., spinal cord).

Diagnostic criteria for rosette-forming glioneuronal tumor (RGNT)

Diagnostic criteria for rosette-forming glioneuronal tumor are shown in ▶ Fig. 40.7.[3]



Rosette-forming glioneuronal tumor

▷ ESSENTIAL ◁

biphasic histomorphology with a neurocytic component and a glial component

AND

uniform neurocytes forming rosettes and/or perivascular pseudorosettes associated with synaptophysin expression

AND (for unresolved lesions)

small biopsies showing only one tumor component (neurocytic or glial) and a methylation profile of rosette-forming glioneuronal tumor

▷ DESIRABLE ◁

- ***FGFR1* mutation with co-occurring *PIK3CA* and/or *NF1* mutation**

Fig. 40.7 Diagnostic criteria for rosette-forming glioneuronal tumor. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Epidemiology

The literature on RGNTs is limited to case reports and single center retrospective studies.[16] Slight female preponderance (male:female ratio of 1:1.36).[17] Mean age is 23.57 years (median 22.5, range 4-49).[16] There is no accepted theory for cytogenesis of these tumors.

Location

RGNTs are typically midline, arise from the 4th ventricle in 42%, and extend into adjacent structures.[16] However, they may also occur in the pineal region, third ventricle, optic chiasm, thalamus and temporal lobe. Spinal cord involvement has also been reported.

Histology

RGNTs demonstrate mixed glial and neuronal elements emblematic of tumors in the class of glioneural tumors.

Imaging

CT: RGNTs are hypodense.

MRI: appearance is variable. They are relatively well circumscribed. Most have solid and cystic components, but they can be either one alone. They tend to be hyperintense on T2WI, and iso- or hypo-intense on T1WI with variable enhancement.

Treatment

Treatment of choice is of choice is gross total resection (GTR) when possible.

Prognosis

Prognosis for OS is favorable. Recurrence is rare after GTR. However, neurologic deficit following surgery is common. Malignant progression has been reported in 2 cases[16]), and may be higher risk with subtotal resection, or with purely solid lesions. RGNTs may disseminate through the CSF.

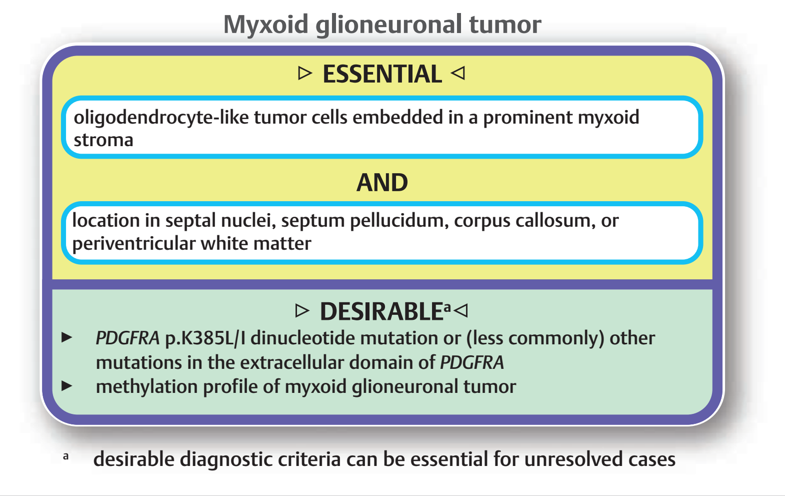
40.1.8 Myxoid glioneuronal tumor (WHO grade 1)

General information

A rare, low-grade glioneuronal tumor with < 100 cases reported to date, that usually occurs in the septal nuclei, septum pellucidum, corpus callosum, or periventricular white matter. Histologically there is a proliferation of oligodendrocyte-like neoplastic cells contained in a myxoid stroma. There is a recurrent dinucleotide mutation at codon p.K385 in the *PDGFRA* gene.

Diagnostic criteria for myxoid glioneuronal tumor

Diagnostic criteria for myxoid glioneuronal tumor are shown in ▶ Fig. 40.8.[3]



Myxoid glioneuronal tumor

▷ ESSENTIAL ◁

AND

location in septal nuclei, septum pellucidum, corpus callosum, or periventricular white matter

▷ DESIRABLE[a] ◁

- ***PDGFRA*** **p.K385L/I dinucleotide mutation or (less commonly) other mutations in the extracellular domain of** ***PDGFRA***
- **methylation profile of myxoid glioneuronal tumor**

[a] **desirable diagnostic criteria can be essential for unresolved cases**

Fig. 40.8 Diagnostic criteria for myxoid glioneuronal tumor. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Imaging

Well circumscribed tumor that is hypointense on T1 and hyperintense on T2 MRI. On SWI, susceptibility artifact may be seen, suggestive of previous hemorrhages. Septal lesions often produce obstructive hydrocephalus.

Prognosis

These slow growing tumors have a favorable prognosis for OS. A subset may recur locally or disseminate through the CSF, but their behavior remains indolent. Dedifferentiation has not been reported.

40.1.9 Diffuse leptomeningeal glioneuronal tumor (DLGNT) (WHO grade 2 or 3)

General information

A glioneuronal neoplasm comprised of oligodendrocyte-like cells that is characterized by chromosome arm 1p deletion and a MAPK pathway gene alteration, typically *KIAA1549*::*BRAF* fusion. Leptomeningeal involvement is common.

Diagnostic criteria for diffuse leptomeningeal glioneuronal tumor

Diagnostic criteria for diffuse leptomeningeal glioneuronal tumor are shown in ▶ Fig. 40.9.[3]

Diffuse leptomeningeal glioneuronal tumor (DLGNT)

▷ ESSENTIAL[a] ◁

oligodendroglioma-like morphology

AND

OLIG2 and synaptophysin immunoreactivity

AND

chromosome arm 1p deletion

AND

MAPK pathway alteration (mostly *KIAA1549::BRAF* fusion)

AND (for unresolved lesions)

methylation profile of diffuse leptomeningeal glioneuronal tumor

▷ DESIRABLE ◁

- childhood onset
- leptomeningeal dissemination

[a] this tumor type shows molecular overlap with pilocytic astrocytoma (*KIAA1549::BRAF* fusion) and oligodendroglioma (1p/19q codeletion). All diffuse leptomeningeal glioneuronal tumors are wildtype in *IDH1* and *IDH2*

Fig. 40.9 Diagnostic criteria for diffuse leptomeningeal glioneuronal tumor. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Subtypes

See reference.[3]

- **diffuse leptomeningeal glioneuronal tumor with 1q gain**
- **diffuse leptomeningeal glioneuronal tumor, methylation class 1 (DLGNT-MC-1)**
- **diffuse leptomeningeal glioneuronal tumor, methylation class 2 (DLGNT-MC-2)**

Grading

Data for grading these tumors is limited. Most DLGNTs are well differentiated low-grade tumors. A subset may show anaplastic features on histology. For cases of conventional DLGNT and DLGNT-MC-1, the behavior has been consistent with WHO grade 2 entities. Whereas tumors with anaplastic features, 1 q gain and/or DLGNT-MC-2 profile have a clinical course more suggestive of a WHO grade 3 lesion.

Location

Predilection for the spinal and intracranial leptomeninges. Intracranially, leptomeningeal growth is tupically observed in the posterior fossa, around the brainstem and along the skull base.

Imaging

MRI usually shows diffuse leptomeningeal enhancement and thickening alongside the spinal cord with intracranial extension to the posterior fossa, brainstem and basal cisterns.

Prognosis

Stability or slow growth over many years may still produce significant morbidity.[18] Decreased survival was associated with mitotic activity, a Ki-67 proliferation index of ≥ 4%, and microvascular proliferation on initial biopsy.[18]

40.1.10 Dysplastic cerebellar gangliocytoma (DCG) (Lhermitte-Duclos disease) (WHO grade 1)

General information

AKA: gangliuneuroma of the cerebellum, purkinjoma, granular cell hypertrophy of the cerebellum, gangliocytoma dysplasticum, hamartoma of the cerebellum.

A cerebellar lesion with features of both a malformation (hamartoma) and a low grade (WHO 1) neoplasm that has a propensity to progress (enlarge) and to recur after surgery. May be focal or diffuse. Cerebellar folia are diffusely enlarged.

Diagnostic criteria for dysplastic cerebellar gangliocytoma

Diagnostic criteria for dysplastic cerebellar gangliocytoma are shown in ▶ Fig. 40.10.[3]

Presentation

Typically a middle-aged *adult* with signs and symptoms of a cerebellar mass such as dysmetria, or they may present with hydrocephalus. It can also be an incidental finding. Cranial nerve deficits may also occur.

Epidemiology

Autosomal dominant. Incidence: 1 in 250,000 live births.[19] Most identified cases have been in adults, but patients as young a 3 years have been reported. Strongly associated with Cowden syndrome (p. 651) (AKA PTEN hamartoma tumor syndrome) where the incidence is 1 in 200,000.[20] Associated with thyroid, breast, and uterine cancer, mucosal neuromas and meningiomas.

Histology

Derangement of normal laminar cellular architecture of the cerebellum with:

1. thickening of the outer molecular cell layer
2. loss of middle Purkinje cell layer
3. infiltration of inner granular cell layer with dysplastic ganglion cells

Dysplastic cerebellar gangliocytoma

▷ ESSENTIAL ◁

gangliocytic lesion enlarging cerebellar folia

AND

densely packed ganglionic cells of various sizes

AND

matrix resembling normal neuropil, sometimes more coarsely fibrillar or vacuolated

▷ DESIRABLE ◁

- *PTEN* mutation/deletion or loss of expression
- abnormal myelination and vacuolization in the outer molecular layer
- calcification and ectatic vessels

Fig. 40.10 Diagnostic criteria for dysplastic cerebellar gangliocytoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Imaging

CT: hypo- to isodense, nonenhancing lesion with mass effect.

MRI: T1WI: hypo- to isointense. T2WI: hyperintense, heterogeneous. Nonenhancing. Characteristic striated appearance[21] (tiger stripes) due to widened cerebellar folia. May contain calcifications. DWI: hyperintense. ADC map: hypointense.

NB: in a child with MRI findings of Lhermitte-Duclos disease (LDD) (even if classic), a medulloblastoma is statistically more likely[22,23] (especially medulloblastoma with extensive nodularity[24] (MBEN)).

Treatment

Controversial. A few cases with a benign course have been described.[25] Shunting is performed for hydrocephalus. Biopsy is recommended[23] particularly for pediatric cases to rule out medulloblastoma. Surgical excision may be considered when there is significant mass effect.[26] Efficacy of XRT is unknown.

Prognosis

Most patients are cured by surgery when indicated. Since DCG may be a harbinger of Cowden syndrome, patients should be monitored for other tumors, e.g., breast and thyroid cancer.

40.2 Neuronal tumors

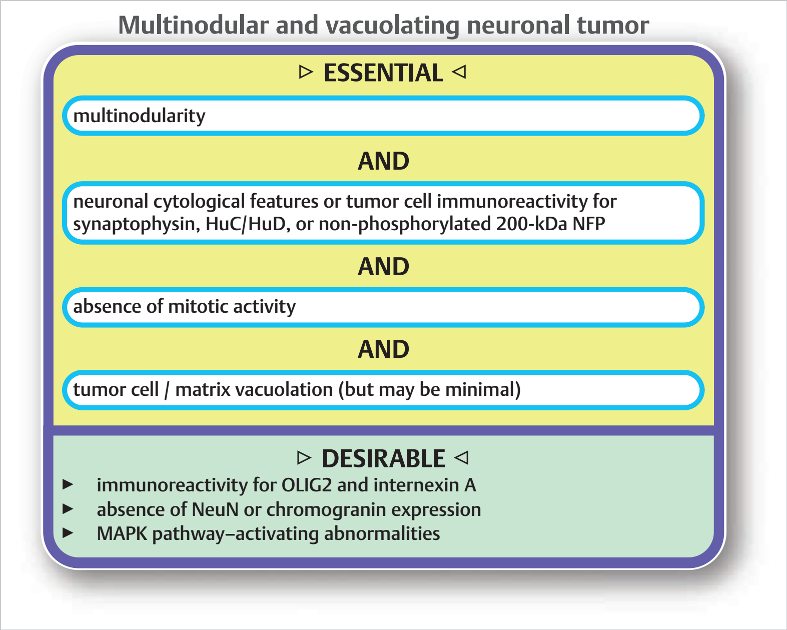
40.2.1 Multinodular and vacuolating neuronal tumor (MVNT) (WHO grade 1)

General information

A rare tumor (17 case reports as of 2018[27]) comprised of uniform neuronal elements dispersed in discrete nodules with vacuolar changes. MVNTs favor the temporal lobes and characteristically involve the deep cortical ribbon and superfical white matter.

Diagnostic criteria for multinodular and vacuolating neuronal tumor

Diagnostic criteria for multinodular and vacuolating neuronal tumor are shown in ▶ Fig. 40.11.[3]



Multinodular and vacuolating neuronal tumor

▷ ESSENTIAL ◁

multinodularity

AND

neuronal cytological features or tumor cell immunoreactivity for synaptophysin, HuC/HuD, or non-phosphorylated 200-kDa NFP

AND

absence of mitotic activity

AND

tumor cell / matrix vacuolation (but may be minimal)

▷ DESIRABLE ◁

- immunoreactivity for OLIG2 and internexin A
- absence of NeuN or chromogranin expression
- MAPK pathway–activating abnormalities

Fig. 40.11 Diagnostic criteria for multinodular and vacuolating neuronal tumor. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Location

There is a predilection for the temporal lobes (75-80%) and frontal lobes (10-15%).[27]

Presentation

The most common presentation is seizures (60%) which may be complex partial ± secondary generalization, followed by headache (10-15%).

Prognosis

These are benign neoplasms. Following gross total excision there are no reports of recurrence, and subtotally resected tumors have not progressed.

40.2.2 Central neurocytoma (WHO grade 2)

General information

Key concepts

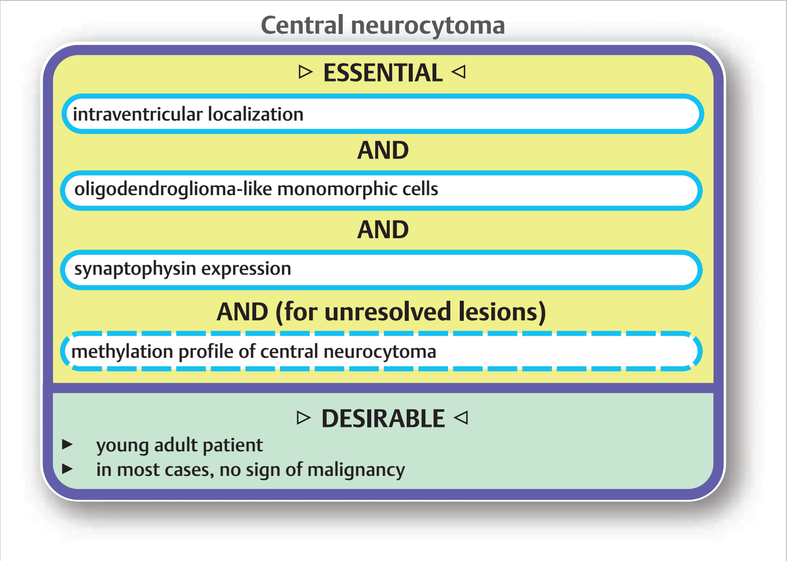
- rare, WHO grade 2 neuronal tumor primarily seen in young adults
- typically intraventricular, attached to septum pellucidum
- gross total resection can be curative (but some recur even after GTR)
- if MIB-1 labeling index > 2–4%, there is an increased risk of recurrence after subtotal resection
- if MIB-1 labeling is elevated, radiation therapy after subtotal resection can reduce the risk of recurrence

Central neurocytomas are rare WHO grade 2 neuronal tumors. They are generally attached to the septum pellucidum within the lateral ventricles, and less frequently occur within the third ventricle. The most common presentation is with increased intracranial pressure and ventriculomegaly.[28,29] See also differential diagnosis for intraventricular lesions (p. 1667).

Due to an uncertain relation of prognosis to Ki-67 index and anaplastic features, a distinction between a possible grade 1 vs. 2 was not made.[30]

Diagnostic criteria for central neurocytoma

Diagnostic criteria for central neurocytoma are shown in ▶ Fig. 40.12.[3]



Central neurocytoma
▷ ESSENTIAL ◁
intraventricular localization
AND
oligodendroglioma-like monomorphic cells
AND

AND (for unresolved lesions)
methylation profile of central neurocytoma
▷ DESIRABLE ◁
▶ young adult patient
▶ in most cases, no sign of malignancy

Fig. 40.12 Diagnostic criteria for central neurocytoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Epidemiology

Constitutes 0.1–0.5% of brain tumors. Incidence peaks in the 3rd decade, but they can also present in children and the elderly.[31] No gender predominates.

Histology

Central neurocytoma cells have small, round nuclei. Cells often have a “fried egg” appearance on H&E staining, which can mimic oligodendroglioma. There are two primary architectures: honeycomb (also mimicking oligodendroglioma) and fibrillary. Rosettes can also be seen. Immunohistochemistry is often positive for neuronal markers synaptophysin and Neu-N.

Electron microscopy: not necessary for diagnosis.[30] It has been used by some when the diagnosis is not clear, and demonstrates neuronal features, including: a prominent golgi apparatus, parallel microtubules, and dense core neurosecretory granules.[28,29]

Molecular genetics: 1p/19q deletion has not been reported in central neurocytoma, but it can be seen in extraventricular neurocytoma.[32]

Imaging

CT scan: 25–50% of these tumors show calcifications. Tumors are usually iso- to hyperdense, with hypodense areas that represent cystic degeneration.[28]

MRI: Tumors appear heterogeneously isointense on T1 and hyperintense on T2. MR spectroscopy often shows a high glycine peak.[33]

Moderate to strong contrast enhancement occurs on both CT and MR images.[29]

Treatment

1. total resection is often curative. After gross total resection, radiation therapy is generally not necessary[28]
2. subtotal resection can be followed by stereotactic radiosurgery, especially if MIB-1 labeling is > 2–4%[28,29,33,34]
3. chemotherapy for recurrent and inoperable tumors has been reported with many agents, including: alkylating agents (carmustine, cyclophosphamide, ifosfamide, lomustine), platinum-based agents (carboplatin and cisplatin), etoposide, topotecan, and vincristine[33,34]
4. after treatment, patients should have long-term follow-up imaging as surveillance for tumor recurrence[29]

Prognosis

Total resection can be curative.[28,33] Recurrence risk after subtotal resection varies with the MIB-1 labeling index. In a 2004 study of neurocytomas with MIB-1 labeling > 2%, the 5-year local control rate after subtotal resection alone was 7%, but if subtotal resection was followed with radiation therapy it was 70%.[34] In a 2013 study, patients with MIB-1 labeling < 4% had no recurrence at 4 years after subtotal resection. If MIB-1 labeling was > 4% at subtotal resection, recurrence was found in 50% of patients at 2 years and 75% at 4 years.[33] Most local recurrences occur within 3–6 years. Recurrence is more common in extraventricular neurocytoma.[34]

40.2.3 Extraventricular neurocytoma (WHO grade 2)

General information

Extraventricular neurocytoma is a variant of central neurocytoma that is even rarer and that may be located in the cerebral parenchyma, cerebellum, thalamus, brainstem, pineal region, and spinal cord. Histologically, they resemble central neurocytomas but with a wider morphological spectrum. They can be focally infiltrative into surrounding tissue. *FGFR1::TACC1* fusions are frequently identified.

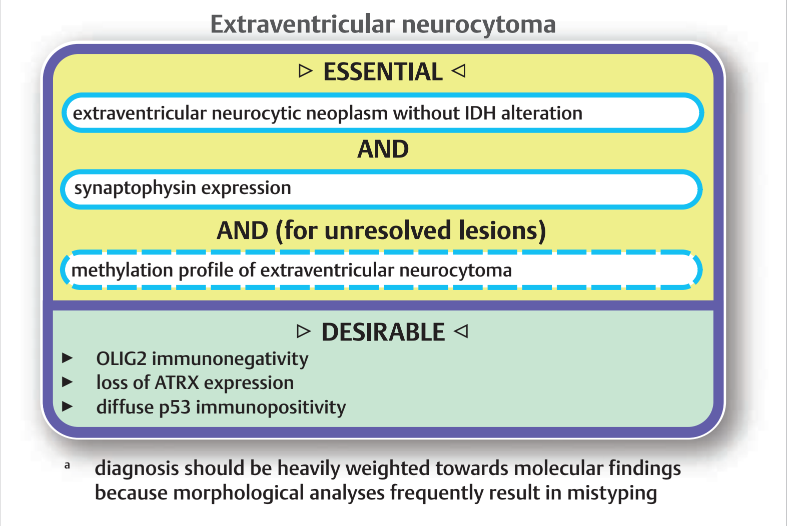
Diagnostic criteria for extraventricular neurocytoma

Diagnostic criteria for extraventricular neurocytoma are shown in ▶ Fig. 40.13.[3]

Histology

Histology is similar to central neurocytoma.

Immunohistochemistry is positive for synaptophysin in the cytoplasm and neuropil. Neu-N staining is often positive.



Extraventricular neurocytoma
▷ ESSENTIAL ◁
extraventricular neurocytic neoplasm without IDH alteration
AND
synaptophysin expression
AND (for unresolved lesions)
methylation profile of extraventricular neurocytoma
▷ DESIRABLE ◁
▶ OLIG2 immunonegativity
▶ loss of ATRX expression
▶ diffuse p53 immunopositivity
a diagnosis should be heavily weighted towards molecular findings because morphological analyses frequently result in mistyping

Fig. 40.13 Diagnostic criteria for extraventricular neurocytoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Central neurocytoma can often be identified by its intraventricular location, however for extraventricular neurocytoma the reactivity for synaptophysin without either IDH mutation or 1p/19q codeletion can differentiate this tumor from oligodendroglioma.

Molecular genetics

The most common genetic alterations are *FGFR1::TACC1* fusions which were found in 60%, while other FGFR alterations were present in 13%.[35] Neither IDH1/2 mutation nor MGMT promoter gene methylation (p. 673) has been reported.[36]

Prognosis

The overall prognosis with this low-grade tumor is favorable. The rate of recurrence has been low and seizure control has been good following gross total resection.

40.2.4 Cerebellar liponeurocytoma (WHO grade 2)

General information

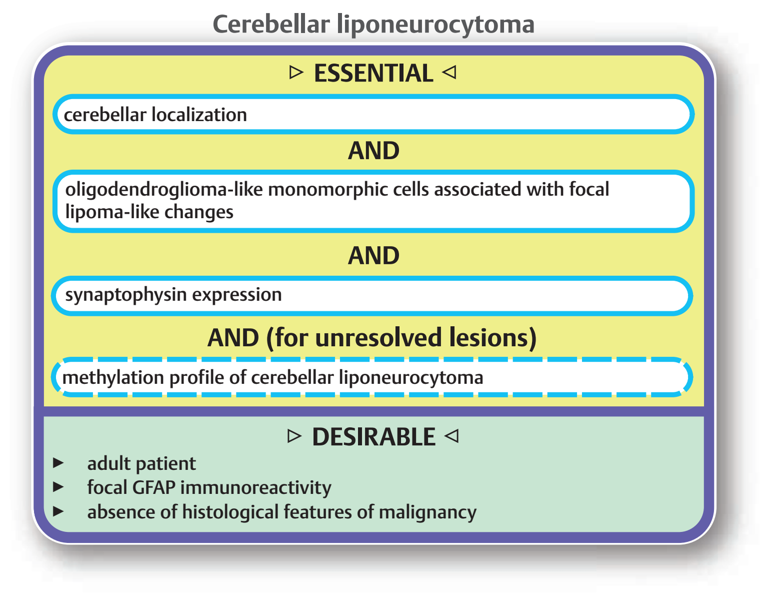
Formerly lipomatous medulloblastoma. A rare WHO grade 2 neoplasm with neuronal/neurocytic differentiation and clusters of neoplastic neurocytes with lipidization (resembling adipocytes) that occurs exclusively in cerebellum (typically in the cerebellar hemispheres, and less commonly the midline or CPA) of adults (mean age: 50 years). No gender preference.

Some authors suggest the more inclusive name “Liponeurocytoma” should replace the separate WHO classification of “Cerebellar liponeurocytoma.” Others contend that the supratentorial exceptions are central neurocytomas which contain neurocytes that underwent lipidization, instead of having actual adipose metaplasia.[37]

40

Diagnostic criteria for cerebellar liponeurocytoma

Diagnostic criteria for cerebellar liponeurocytoma are shown in ▶ Fig. 40.14.[3]



Cerebellar liponeurocytoma
▷ ESSENTIAL ◁
cerebellar localization
AND
oligodendroglioma-like monomorphic cells associated with focal lipoma-like changes
AND

AND (for unresolved lesions)
methylation profile of cerebellar liponeurocytoma
▷ DESIRABLE ◁
► adult patient
► focal GFAP immunoreactivity
► absence of histological features of malignancy

Fig. 40.14 Diagnostic criteria for cerebellar liponeurocytoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Imaging

CT: isodense in areas, with areas of very low density where the fat content is high.

MRI: lipid rich areas are hyperintense on T1 and T2. The suspicion about lipid content is supported when these areas drop out on fat suppression sequences.

Histology

Cells are uniform, neuocytic morphology with regular round to oval nuclei and clear cytoplasm with ill-defined cell mambranes arrayed in sheets and lobules. The distinctive feature are lipid containing cells resembling adipocytes.

Synaptophysin (p. 632) and MAP-2 immunostaining is consistent and diffuse, focal GFAP staining is common. Usually no mitotic figures. MIB-1 index is usually low (mean of 3.73% ± 4.01%).[38]

Prognosis

Cerebellar liponeurocytoma have a favorable prognosis. Following GTR, the 5-year survival rate was 71.3%, PFS rate 61%, mean OS was 16.3 years, and the mean PFS was 10 years.[38] Subtotal resection carried a 42% recurrence rate vs. 15% with GTR.[38] Post-op radiation improved the PFS from 55% (16/29 patients) to 92% (11 out of 12) with median follow-up of 52 months.[38] All recurrences were restricted to the posterior fossa.

41 Ependymal Tumors

41.1 Introduction to ependymal tumors

The WHO CNS5 classified ependymomas by site as well as by histology and molecular biology features.

41.2 Specific tumor types

41.2.1 Supratentorial ependymoma (WHO grade 2 or 3)

General information

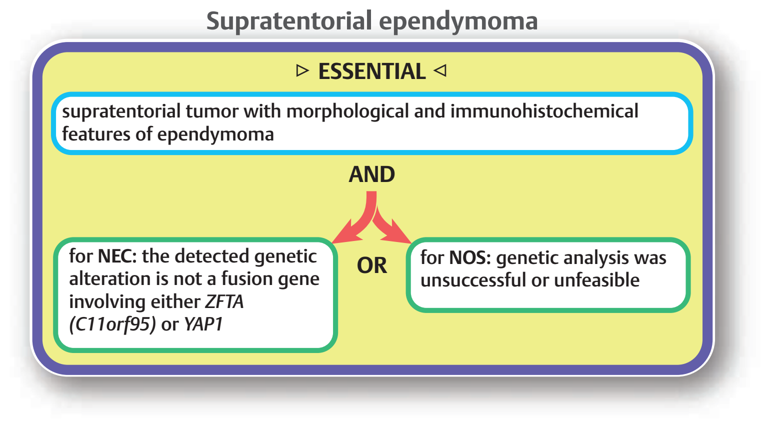
A well-circumscribed supratentorial glioma with small uniform cells having round nuclei that form focal pseudorosettes or ependymal rosettes embedded in a fibrillary matrix. Cells are thought to derive from radial glial cells (bipolar progenitor cells that are thought to be a major source of neurons in the developing nervous system).

The following designations should be used:

- **supratentorial ependymoma, NEC** (not elsewhere classified): when genetic analysis has not identified a pathologic fusion gene involving *ZFTA* (*C11orf95*) or *YAP1*
- **supratentorial ependymoma, NOS** (not otherwise specified): when genetic analysis has not been successful or is not feasible

Diagnostic criteria for supratentorial ependymoma

Diagnostic criteria for supratentorial ependymoma are shown in ▶ Fig. 41.1.[1]



supratentorial tumor with morphological and immunohistochemical features of ependymoma

for **NEC**: the detected genetic alteration is not a fusion gene involving either *ZFTA* (*C11orf95*) or *YAP1*

for **NOS**: genetic analysis was unsuccessful or unfeasible

Fig. 41.1 Diagnostic criteria for supratentorial ependymoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Grading

The most important characteristics distinguishing grade 3 supratentorial ependymomas from grade 2 are abundant mitoses and the presence of microvascular proliferation. These are more influential than nuclear pleomorphism or necrosis.[2] NB: histopathological grading of ependymomas is not highly correlated with overall outome.

Location

These tumors are found in the cerebral hemispheres. A connection to the ventricular system may or may not be obvious. They favor the frontal or parietal lobes over the temporal or occipital lobes.

Epidemiology

These tumors affect all ages, but the proportion relative to the posterior fossa and spinal ependymomas decreases with age.[3] They comprise ≈ one third of intracranial ependymomas.

Prognosis

Most of the data comes from studies performed before molecular testing. The outcome is worse for supratentorial than infratentorial ependymomas in adults.

Gross total removal is the most important prognosticator of OS in adults and children. Post-op XRT lowers the risk of local recurrence.

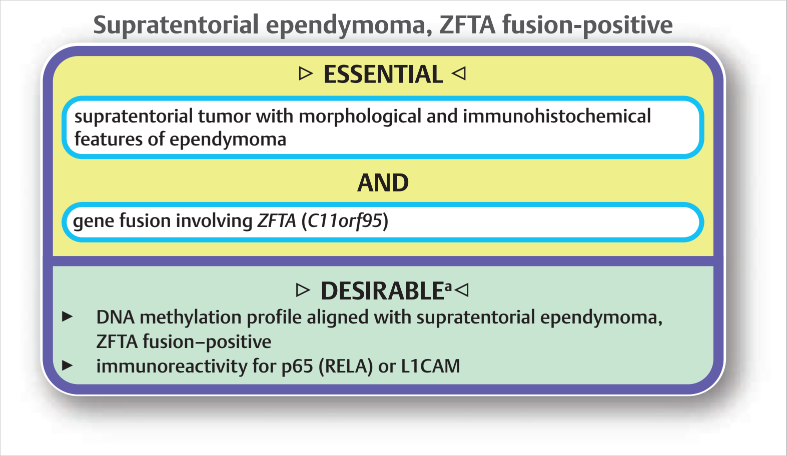
41.2.2 Supratentorial ependymoma, ZFTA fusion-positive (WHO grade 2 or 3)

General information

A well-circumscribed supratentorial glioma with a *ZFTA* (formerly *C11orf95*) fusion gene (typically *ZFTA* is fused with *RELA*), with small uniform cells having round nuclei containing speckled chromatin and poorly delineated fibrillary cytoplasm. Pseudorosettes are usually not prominent, and true ependymal rosettes embedded are infrequent. There is often a network of branching capillary vasculature. Cells are thought to derive from radial glial cells.

Diagnostic criteria for supratentorial ependymoma, ZFTA fusion-positive

Diagnostic criteria for supratentorial ependymoma, ZFTA fusion-positive are shown in ▶ Fig. 41.2.[1]



Supratentorial ependymoma, ZFTA fusion-positive

▷ ESSENTIAL ◁

supratentorial tumor with morphological and immunohistochemical features of ependymoma

AND

gene fusion involving *ZFTA* (*C11orf95*)

▷ DESIRABLE[a] ◁

- DNA methylation profile aligned with supratentorial ependymoma, ZFTA fusion–positive
- immunoreactivity for p65 (RELA) or L1CAM

Fig. 41.2 Diagnostic criteria for supratentorial ependymoma, ZFTA fusion-positive. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Grading

These tumors are considered WHO grade 2 or 3 based on the degree of anaplasia observed.

Location

Most of these tumors are found in the frontal or parietal lobes. They occur infrequently in the thalamus, hypothalamic/thrid ventricular region, or extra-axially.

Epidemiology

Supratentorial ependymoma, ZFTA fusion-positive tumors comprise the majority of supratentorial ependymomas (20-58% in adults, 66-84% in pediatrics).[1]

Prognosis

Preliminary data suggest a worse outome than with other ependymomas, however, more experience with this recently molecularly defined group will be needed to make any definitive statements. Homozygous deletion of *CDKN2A* and/or *CDKN2B* are independent risk factors for worse OS in a series of supratentorial ependymomas with *ZFTA*::*RELA* fusions.[4]

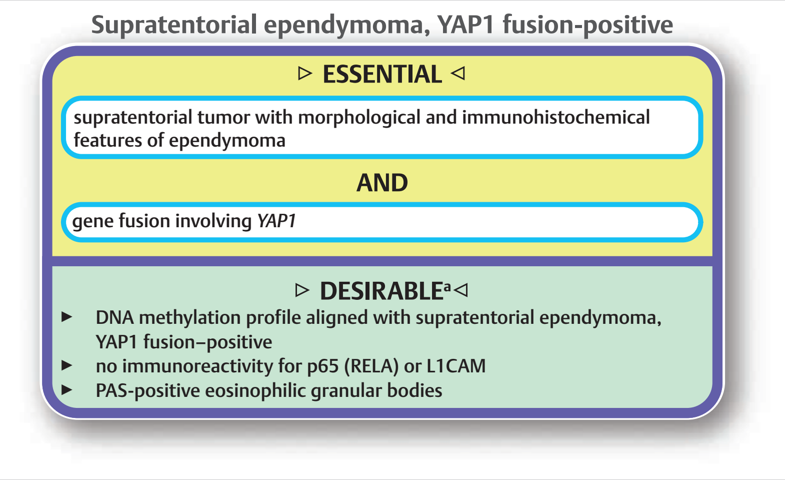
41.2.3 Supratentorial ependymoma, YAP1 fusion-positive (WHO grade N/A)

General information

A well circumscribed supratentorial glioma with a *YAP1* fusion gene (typically YAP1 is fused with *MAMLD1*), with small uniform cells having round nuclei that form focal pseudorosettes or ependymal rosettes embedded in a fibrillary matrix. Cells are thought to derive from PAX6-positive radial glial neural stem cells.

Diagnostic criteria for supratentorial ependymoma, YAP1 fusion-positive

Diagnostic criteria for supratentorial ependymoma, YAP1 fusion-positive are shown in ► Fig. 41.3.[1]



Supratentorial ependymoma, YAP1 fusion-positive

▷ ESSENTIAL ◁

supratentorial tumor with morphological and immunohistochemical features of ependymoma

AND

gene fusion involving *YAP1*

▷ DESIRABLE[a] ◁

- DNA methylation profile aligned with supratentorial ependymoma, YAP1 fusion–positive
- no immunoreactivity for p65 (RELA) or L1CAM
- PAS-positive eosinophilic granular bodies

Fig. 41.3 Diagnostic criteria for supratentorial ependymoma, YAP1 fusion-positive. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Location

These tumors are usually found within or adjacent to the lateral ventricle.

Epidemiology

Supratentorial ependymoma, YAP1 fusion-positive tumors seem to be isolated to young children, and show a M:F ratio of 0.3:1.[1] They account for 6-7.4% of supratentorial ependymomas in pediatric cohorts.[1]

Prognosis

Prognosis appears favorable compared to other supratentorial ependymomas (retrospective analysis).[1]

41.2.4 Posterior fossa ependymoma (WHO grade 2 or 3)

General information

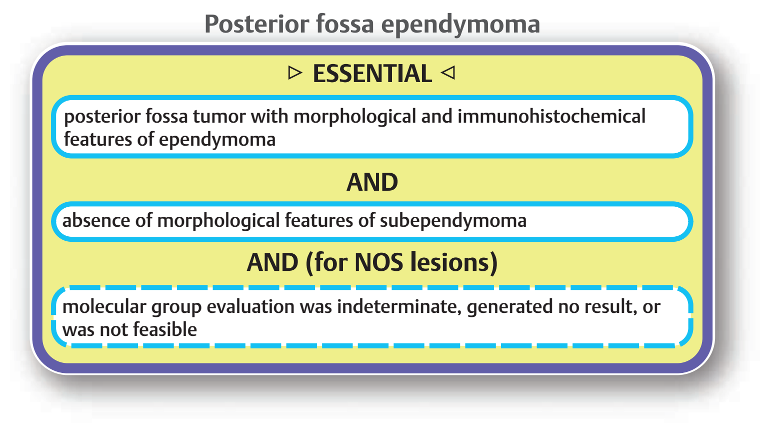
Key concepts

- usually benign tumors, often fibrillary with epithelial appearance. Perivascular pseudorosettes or ependymal rosettes may be seen
- most often occur in the floor of the 4th ventricle, presenting with hydrocephalus (increased ICP) and cranial nerve VI & VII palsies
- evaluation: includes imaging the entire neuraxis (MRI with and without enhancement: cervical, thoracic, lumbar & brain) because of potential for seeding through CSF
- worse prognosis the younger the patient (especially age < 24 months)
- treatment: the best outcomes are associated with gross total removal (no enhancing tumor on post-op MRI) followed by XRT. XRT may be withheld for age < 3 years due to side effects
- do LP ≈ 2 weeks post-op to send ≈ 10 cc of CSF for cytology for prognostication

A circumscribed posterior fossa glioma of monomorphic round cells with round nuclei that form focal pseudorosettes or ependymal rosettes embedded in a fibrillary matrix. This diagnosis should be employed when molecular analysis cannot assign a molecular group (NEC, not elsewhere classified) or is not feasible or the results were uncertain (NOS, not otherwise specified)

Diagnostic criteria for posterior fossa ependymoma

Diagnostic criteria for posterior fossa ependymoma are shown in ▶ Fig. 41.4.[1]



Posterior fossa ependymoma

▷ ESSENTIAL ◁

posterior fossa tumor with morphological and immunohistochemical features of ependymoma

AND

absence of morphological features of subependymoma

AND (for NOS lesions)

molecular group evaluation was indeterminate, generated no result, or was not feasible

Fig. 41.4 Diagnostic criteria for posterior fossa ependymoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Grading

Should ideally be done in the context of an integrated diagnosis.[2] The most important characteristics distinguishing grade 3 posterior fossa ependymomas from grade 2 are abundant mitoses and the presence of microvascular proliferation. These are more influential than nuclear pleomorphism or necrosis.[2] NB: histopathological grading of ependymomas is not highly correlated with overall outome.

Location

These tumors generally occur in relation to the 4th ventricle (floor, lateral aspect, cerebellar peduncles, or roof).

Spread

Ependymomas have the potential to spread via the CSF through the neuraxis (including to the spinal cord), a process known as “seeding,” resulting in so-called **“drop mets”** in the spinal cord in 11%. The incidence is higher with higher grade.[5] Systemic spread occurs on rare occasions.

Presentation

Mostly those of posterior fossa mass with increased ICP (from hydrocephalus) and cranial nerve involvement.

► **Symptoms.** Symptoms of increased ICP:

1. headache
2. N/V
3. ataxia or vertigo
4. obtundation/lethargy

Symptoms of cranial nerve involvement: diplopia, facial weakness…

► **Signs.** In infants: increasing head circumference crossing growth curves.

Cranial nerve involvement: invasion of the floor of the 4th ventricle may impact the facial colliculus (a small bump in the floor of the 4th ventricle produced by the internal genu of the VII nerve as it deviates posteriorly around the VI nerve nucleus). This can produce peripheral facial nerve palsy (p. 607) (from VII nerve) and/or abducens palsy (p. 598) (from VI nucleus).

Imaging

MRI: the imaging study of choice. The entire craniospinal axis should be imaged with and without contrast because of possibility of drop mets. Usually appears as a mass in the floor of fourth ventricle (► Fig. 41.5), or when large it can fill the 4th ventrical and extension through the foramina of Luschka and/or Magengie may be seen. The tumor enhances except for cystic portions or areas of necrosis. Obstructive hydrocephalus is often identified at presentation. May be difficult to distinguish from medulloblastoma radiographically, see differentiating features (p. 1647).

CT: not as detailed for evaluation of posterior fossa.

Myelogram: water-soluble contrast myelography with CT is about as sensitive as gadolinium enhanced MRI in detecting “drop mets.” Myelography can also provide CSF for cytology for staging purposes.

Epidemiology

Posterior fossa ependymomas of all of the types can occur at any age, but the median age at presentation is 6 years, with a slight male predominance.

Treatment

Surgical resection

Goal of surgery: maximal possible resection of intracranial portion without causing neurological deficits (since extent of resection is an important prognosticator). Gross total resection may not be possible when invasion of the floor is extensive, or when tumor extends through the foramen of Luschka (bradycardia may prevent GTR).

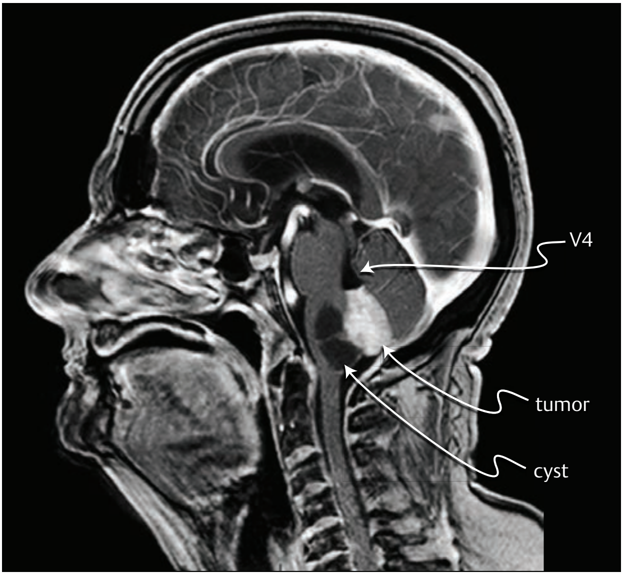


Fig. 41.5 Ependymoma (WHO grade 2) of the posterior fossa in a 71-year-old woman.
Here, the tumor arises from the floor of the 4th ventricle and has a cystic component that invades the medulla. It displaces but does not invade the cerebellum. The 4th ventricle (V4) is obstructed and the patient had hydrocephalus.
Image: sagittal T1 contrast-enhanced MRI.

These tumors are usually circumscribed with a covering layer of ependyma, and are only rarely invasive to a significant degree.[6]

Operative morbidity: advise patients/families pre-op of the likelihood of need for post-op gastric feeding tube (G-tube) and tracheostomy (these may be temporary).

2 weeks postoperatively, perform LP to look for “drop mets”: 10 cc of CSF is sent for cytology to quantitate (if any) number of malignant cells (may be used to follow treatment). If LP is positive, then by definition there are drop mets. If negative, it is not as helpful (sensitivity is not high). CSF from an EVD is not as sensitive as LP.

Lesions in fourth ventricle region are approached via midline suboccipital craniectomy.

Radiation therapy (XRT)

Ependymomas rank 2nd only to medulloblastomas in radiosensitivity. XRT is administered after surgical excision (survival is improved with post-op XRT[7,8]: 50% survival time was 2 yrs longer with XRT than without,[7] and 5-year survival increased from 20–40% without XRT to 40–80% with XRT[8]); however, for patients age < 3 years, see below.

1. cranial XRT
   a) traditional therapy: 45–48 Gy to tumor bed[8] (recurrence treated with additional 15–20 Gy)[9 (p 2797)]
   b) recent recommendations: 3-D conformal XRT with higher doses (59.4 Gy delivered to tumor bed + 1 cm margins)[10]
   c) intensity modulated proton beam therapy appears equivalent in terms of local control, but may be better at sparing normal tissue[11]
2. spinal XRT: most radiate only if drop mets or if positive CSF cytology (however, prophylactic spinal is controversial[12])
   a) low dose XRT to entire spinal axis (median dose = 30 Gy in one series[8])
   b) boost to any regions showing drop mets

3. XRT is undesirable in age < 3 years due to side effects. XRT was avoided in ≈ 30% of patients < 3 years of age with comparable survival when XRT was reserved for treatment failures.[13,14] This concept of selective XRT may be applicable to older children as well[15]

Chemotherapy

Role is very limited.

1. has little impact on newly diagnosed cases. Adjuvant chemo after XRT in patients > 3 years showed no benefit
2. may reduce vascularity of ependymomas, which may facilitate GTR (sometimes in a second stage operation)
3. may be considered for infants < ≈ 3 years of age to delay use of XRT (see above)
4. chemo at the time of recurrence may arrest tumor progression for short periods

Prognosis

Extent of resection: the risk of recurrence is highest following subtotal resection. Gross total resection (GTR) (surgical) of primary intracranial tumor followed by craniospinal XRT as outlined above yields 41% 5-year survival.

Treatment failure: tumors tend to recur initially at the site of origin.[16] However, treatment failure in 9–25% of patients is due to drop mets.[17,18]

Age: peds vs. adults: 5-year survival (5YS) is 20–30% in the pediatric group,[5,19] compared with up to 80% in adults. Patients 24–35 months old did better (73% 5YS) than those younger than 24 months (26% 5YS) or those older than 36 months (36% 5YS).[17]

41.2.5 Posterior fossa group A (PFA) ependymoma (WHO grade 2 or 3)

General information

PFA ependymoma is a circumscribed posterior fossa glioma aligned with the PFA molecular groups of ependymomas (loss of nuclear H3 p.K28me3 (K27me3) expression in tumor cells or by DNA methylation profiling) having small uniform cells with round nuclei that form focal pseudorosettes or ependymal rosettes embedded in a fibrillary matrix. Cells are thought to derive from undifferentiated glial stem or progenitor cell in the developing hindbrain.

Diagnostic criteria for posterior fossa group A (PFA) ependymoma

Diagnostic criteria for posterior fossa group A (PFA) ependymoma are shown in ▶ Fig. 41.6.[1]

Grading

Grading of WHO grade 2 or 3 is based on the degree of anaplasia and reported in an integrated diagnosis.[2]

Location

These tumors arise more frequently from the roof or lateral aspect of the 4th ventricle.

Presentation

Similar to the presentation of posterior fossa ependymomas (p. 728) in general.

Epidemiology

PFA ependymomas predominantly occur in pre-adolescents with a median age of 3 years at presentation.[1]

Prognosis

Prognosis appears less favorable than with PFB ependymomas.[20] Extent of resection correlates with outcome.[21] Tiers of disease risk can be defined using chromosome 1q status and other variables.[21]

(series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

41.2.6 Posterior fossa group B (PFB) ependymoma (WHO grade 2 or 3)

General information

PFB ependymoma is a circumscribed posterior fossa glioma aligned with the PFB molecular groups of ependymomas (by DNA methylation profiling) having small uniform cells with round nuclei that form focal pseudorosettes or ependymal rosettes embedded in a fibrillary matrix.[1]

Diagnostic criteria for posterior fossa group B (PFB) ependymoma

Diagnostic criteria for posterior fossa group B (PFB) ependymoma are shown in ▶ Fig. 41.7.[1]

Grading

Grading of WHO grade 2 or 3 is based on the degree of anaplasia and reported in an integrated diagnosis.[2] High-grade features, including brisk mitotic activity and microvascular proliferation, were observed in 41% of PFB ependymomas.[20]

Location

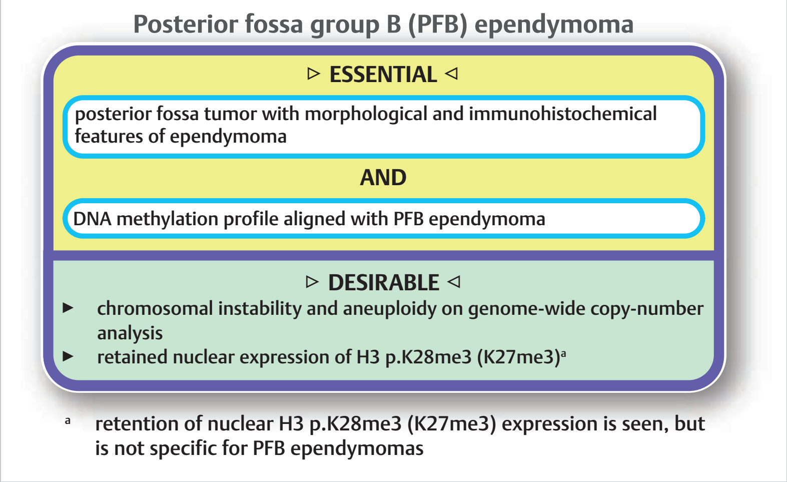
These tumors arise more frequently from the floor of the 4th ventricle.

Presentation

Similar to the presentation of posterior fossa ependymomas (p. 728) in general.

Epidemiology

PFB ependymomas are more common in adults and adolescents than in pre-adolescents, with a median age of 30 years (range: 1-72) at presentation.[1]



Posterior fossa group B (PFB) ependymoma

▷ **ESSENTIAL** ◁

posterior fossa tumor with morphological and immunohistochemical features of ependymoma

- **retained nuclear expression of H3 p.K28me3 (K27me3)[a]**

[a] **retention of nuclear H3 p.K28me3 (K27me3) expression is seen, but is not specific for PFB ependymomas**

Fig. 41.7 Diagnostic criteria for posterior fossa group B (PFB) ependymoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Prognosis

Subtotal resection and loss of 13q correlated with a poor prognosis, and gain of 1q did not appear to be correlated to OS.[22]

41.2.7 Spinal ependymoma (WHO grade 2 or 3)

General information

Spinal ependymomas are circumscribed intramedullary spinal gliomas having small uniform cells with round nuclei that form focal pseudorosettes or ependymal rosettes embedded in a fibrillary matrix. They typically have low levels of mitoses. Features of myxopapillary ependymoma or subependymoma are absent, by definition. *MYCN* amplification is absent when testing is possible.[1]

Diagnostic criteria for spinal ependymoma

Diagnostic criteria for spinal ependymoma are shown in ▶ Fig. 41.8.[1]

Grading

The vast majority of spinal ependymomas are WHO grade 2, with grade 3 tumors being rare. Grade 3 tumors have brisk mitotic activity, high cell density, and tend to invade adjacent spinal cord structures.

Location

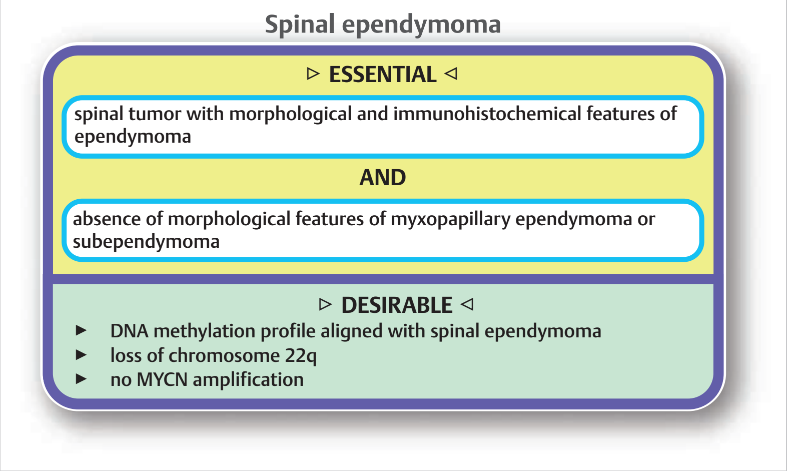
These tumors arise anywhere along the spinal canal, but favor cervical or cervicothoracic levels.

Presentation

See presentation of intramedullary spinal cord tumors (p. 986).

Epidemiology

Spinal ependymomas comprise 17% of primary spinal tumors in the U.S.[23]



Spinal ependymoma

▷ **ESSENTIAL** ◁

AND

absence of morphological features of myxopapillary ependymoma or subependymoma

▷ **DESIRABLE** ◁

- DNA methylation profile aligned with spinal ependymoma
- loss of chromosome 22q
- no MYCN amplification

Fig. 41.8 Diagnostic criteria for spinal ependymoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Imaging

These are intramedullary tumors that are low intensity on T1 MRI, hyperintense on T2, and enhance readily. They tend to be more centrally located and more readily defined than spinal astrocytomas which are often eccentric and poorly demarcated.[24] 22% have a tumor cyst, and 62% are associated with a nontumoral cyst (e.g., syringomyelia).[24] Necrosis or calcifications may be seen.

Prognosis

Prognosis for grade 2 spinal ependymomas is favorable with PFS rates of 70% in children and 90% in adults over 5-10 years, and OS of 90% in children and 100% in adults over the same period.[25] Unfortunately, late recurrence is not uncommon.[26] The prognosis for grade 3 tumors is poor.[25]

41.2.8 Spinal ependymoma, MYCN-amplified (WHO grade N/A)

General information

MYCN-amplified spinal ependymomas are rare, circumscribed intramedullary spinal gliomas having small uniform cells with round nuclei that form focal pseudorosettes or ependymal rosettes embedded in a fibrillary matrix. Essentially all tumors demonstrate microvascular proliferation, necrosis and brisk mitotic activity. By definition, *MYCN* amplification is present.[1]

Diagnostic criteria for spinal ependymoma, MYCN-amplified

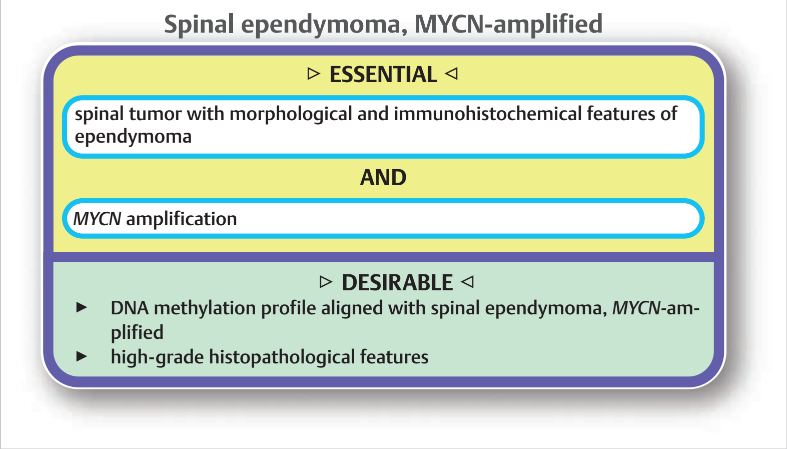
Diagnostic criteria for spinal ependymoma, MYCN-amplified are shown in ▶ Fig. 41.9.[1]

Grading

A WHO grade has not yet been asigned to these tumors.

Location

78% of cases involved the cervical or thoracic spinal cord, and 7% lumbar. They may be intramedullary, intramedullay with exophytic component, or mostly extramedullary. Leptomeningeal is frequent at diagnosis, or eventually occurs during the course.[1]



Spinal ependymoma, MYCN-amplified

World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Presentation

See presentation of intramedullary spinal cord tumors (p. 986).

Epidemiology

Only 27 cases were reported at the time the WHO CNS5 classification was published. 17 occurred in women, 10 in men. The median age at presentation was 31 years, with a range of 12-56 years.[1]

Imaging

These are intramedullary tumors that are low intensity on T1 MRI, hyperintense on T2, and enhance avidly. They tend to be more centrally located and more readily defined than spinal astrocytomas which are often eccentric and poorly demarcated.[24] 22% have a tumor cyst, and 62% are associated with a nontumoral cyst (e.g., syringomyelia).[24] Necrosis or calcifications may be seen.

Prognosis

Prognosis is poor for PFS and OS. Early spread throughout the neuraxis is frequent. Recurrence occurred in all patients with follow-up.[1]

41.2.9 Myxopapillary ependymoma (WHO grade 2)

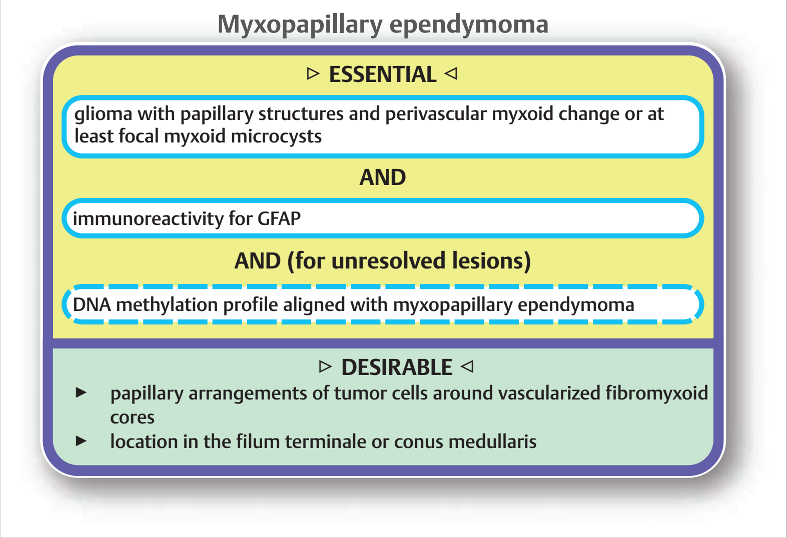
General information

A distinctive variant of ependymoma. A WHO grade 2 glial neoplasm that essentially only occurs in the conus medullaris (the inferior terminus of the spinal cord) or the filum terminale (connective tissue band that extends inferiorly from the conus medullaris) characterized by tumor cells radially arranged around blood vessels with perivascular myxoid changes and microcyst formation.

Staining for GFAP can help differentiate this tumor from metastatic carcinoma, paragangliomas, schwannomas, chordomas, and myxoid chondrosarcomas.

Diagnostic criteria for myxopapillary ependymoma

Diagnostic criteria for smyxopapillary ependymoma are shown in ▶ Fig. 41.10.[1]



Myxopapillary ependymoma

▷ ESSENTIAL ◁

glioma with papillary structures and perivascular myxoid change or at least focal myxoid microcysts

AND

immunoreactivity for GFAP

AND (for unresolved lesions)

DNA methylation profile aligned with myxopapillary ependymoma

▷ DESIRABLE ◁

- papillary arrangements of tumor cells around vascularized fibromyxoid cores
- location in the filum terminale or conus medullaris

Fig. 41.10 Diagnostic criteria for myxopapillary ependymoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Treatment

Complete removal is often not possible due to invasion of the spinal cord parenchyma and/or CSF dissemination which is more common in pediatrics.

The high recurrence rate is an argument for early use of post-resection XRT, but proof of benefit in large series is lacking.[25]

Prognosis

Prognosis is relatively favorable with 10-year survival rates > 90% in adults and children.

41.2.10 Subependymoma (WHO grade 1)

General information

Key concepts

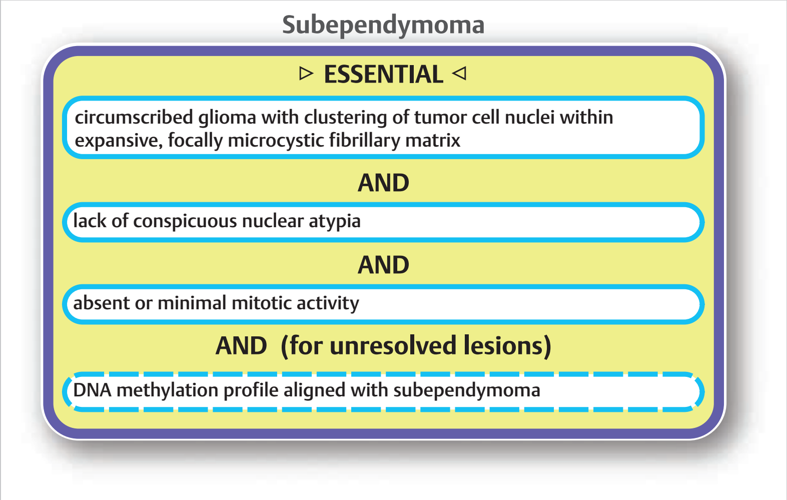
- slow growing, WHO grade 1 tumor
- arise from ependymal lining of, and protrude into, the ventricle. Noninvasive
- one of the only intraventricular tumors (excluding colloid cysts) that does not enhance
- almost always an incidental finding; hydrocephalus when symptomatic
- treatment: most are observed with serial imaging. Gross total removal, when possible, is the goal if intervention is indicated

A slow growing (WHO grade 1) glioma arising from the ependymal lining of the ventricles characterized by clusters of bland to mildly pleomorphic cells in a fibrillary matrix, often with microcysts. Cells are mitotically inactive. 50-60% occur in the 4th ventricle, 30-40% in the lateral ventricles.

The tumors protrude into the ventricle and are noninvasive.

Diagnostic criteria for subependymoma

Diagnostic criteria for subependymoma are shown in ▶ Fig. 41.11.[1]



Subependymoma

▷ ESSENTIAL ◁

circumscribed glioma with clustering of tumor cell nuclei within expansive, focally microcystic fibrillary matrix

AND

lack of conspicuous nuclear atypia

AND

absent or minimal mitotic activity

AND (for unresolved lesions)

DNA methylation profile aligned with subependymoma

Fig. 41.11 Diagnostic criteria for subependymoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Epidemiology

Reliable data on incidence is difficult to come by since the majority are asymptomatic. A SEER registry database analysis found an incidence of 0.055 cases per 100,000 person years and a M:F ratio of about 2.5:1, and a peak incidence in adults 40-84 years old.[27]

Subependymomas make up ≈ 8% of ependymal tumors and < 1% of intracranial neoplasms.

Presentation

almost always an incidental finding on imaging performed for some other reason. The unusual exception to this is when a subependymoma causes obstructive hydrocephalus.

Neuroimaging

The typical appearance is a nonenhancing well-demarcated intraventricular mass (▶ Fig. 41.12). There are differences of opinion of the tendency for subependymomas to enhance; Jelinek et al[28] found that they did not. Also see differential diagnosis for intraventricular lesions (p. 1667).

Treatment

Almost always an incidental finding on imaging performed for some other reason. The unusual exception to this is when a subependymoma causes obstructive hydrocephalus.

Tumors meeting the typical imaging characterstics of subependymomas may be monitored with serial imaging. Usually the first follow-up image is obtained 3 months after initial discovery to rule out a mimic with rapid growth. Then, annual imaging should be done for a period of time (e.g., 5 years) and then at a less frequent basis.

Prognosis

Prognosis is excellent. When treatment is indicated, gross total resection (GTR) when possible is almost always curative. When GTR is not possible (e.g., tumors arising from the floor of the 4th ventricle) subtotal resection is usually satisfactory since the tumors are so slow growing.

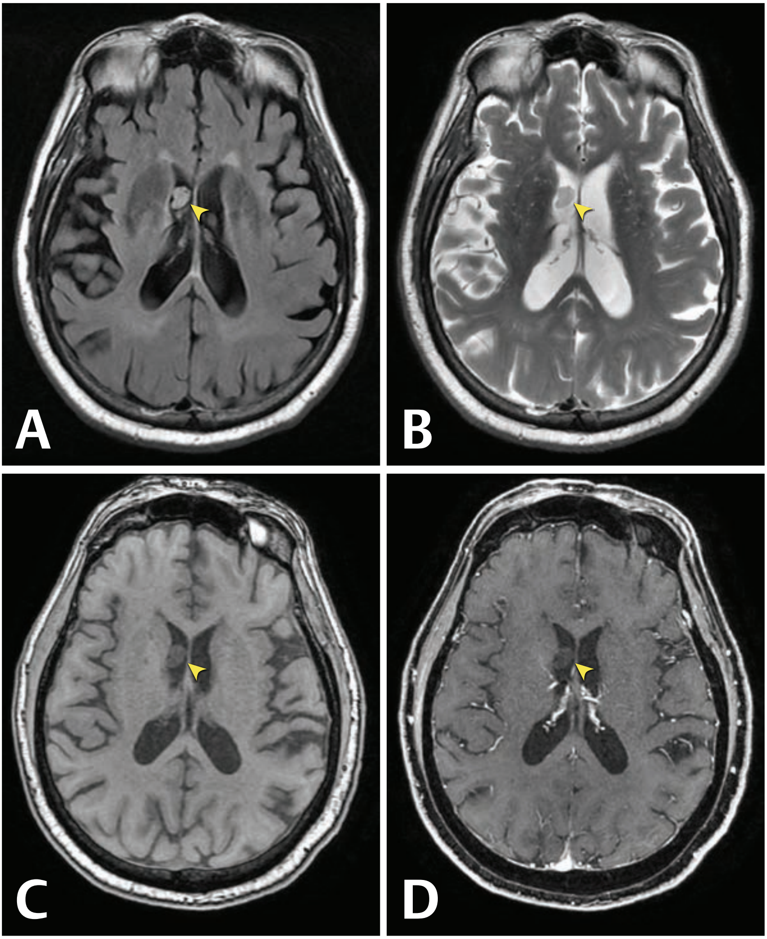


Fig. 41.12 Subependymoma (presumed, not biopsy proven). The lesion (*yellow arrowheads*) has remained unchanged over 10 years of observation.
Image: axial MRI A: FLAIR, B: T2, C: T1 non-contrast, D: T1 with contrast (note the lack of enhancement).

42 Choroid Plexus Tumors

42.1 General information

Choroid plexus tumors can occur anywhere there is choroid plexus. This is one of several groups of tumors with a younger median age at diagnosis than other histologies.[1]

Most are histologically benign.

All may produce drop mets in the CSF, but WHO grade 3 choroid plexus carcinomas do so more commonly.

Malignant degeneration from WHO grade 1 or 2 to grade 3 was seen in 2 out of 124 patients with 59 months mean follow-up.[2]

42.2 Choroid plexus tumor types

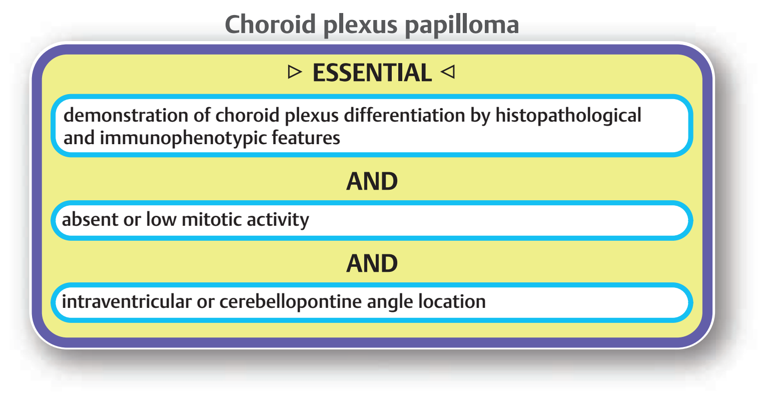
42.2.1 Choroid plexus papilloma (CPP) (WHO grade 1)

General information

A benign (WHO grade 1) intraventricular neoplasm resembling normal choroid plexus, with little or no mitotic activity.

Diagnostic criteria for choroid plexus papilloma

Diagnostic criteria for choroid plexus papilloma are shown in ▶ Fig. 42.1.[3]



Choroid plexus papilloma

▷ ESSENTIAL ◁

demonstration of choroid plexus differentiation by histopathological and immunophenotypic features

AND

absent or low mitotic activity

AND

intraventricular or cerebellopontine angle location

Fig. 42.1 Diagnostic criteria for choroid plexus papilloma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Location

CPP are most frequently found in the lateral ventricles (with a predilection for the left side), followed by the fourth ventricles and then third ventricles. Rare ectopic cases have been reported. They may be found in the CPA from extension of choroid plexus through the foramen of Luschka. In adults these tumors are usually infratentorial, whereas in children they tend to occur supratentorially (a reverse from the situation for most other tumors) in the lateral ventricle.[4] See Intraventricular lesions (p. 1667) for differential diagnosis.

Epidemiology

Although they may occur at any age, 70% of patients are < 2 yrs old.[5] About 80% of lateral ventricle CPPs occur in patients < 20 years of age, unlike fourth ventricluar CPPs which are evenly distributed among all ages.[6]

CPP comprise 2.1% of all primary and CNS tumors in the U.S.,[1] and 2.1% of brain tumors in individuals < 15 years of age, and 10–20% of brain tumors in the first year of life. A portion of these tumors occur in neonates, supporting the hypothesis that some of these are congenital.[4]

Presentation

Most present with symptoms of increased ICP from hydrocephalus (H/A, N/V, craniomegaly), others may present with seizures, subarachnoid hemorrhage (with meningismus), or focal neurologic deficit (hemiparesis, sensory deficits, cerebellar signs, or cranial nerve palsies of III, IV, and VI).

Hydrocephalus, which may result from: overproduction of CSF (although total removal of these tumors does not always cure the hydrocephalus—especially in patients with high CSF protein, hemorrhage from tumor or surgery, or ependymitis), obstruction of CSF outflow, or communicating hydrocephalus from CSF-borne particulates.

Imaging

CT: iso- to hyper-dense.

MRI: T1 isointense, T2 hyperintense.

CT or MRI: intraventricular multilobulated mass, classically with projecting “fronds.” Densely enhancing. Hydrocephalus is common.

Treatment & prognosis

CPP are often cured surgically with total removal.

The operation may be difficult due to fragility of the tumor and bleeding from the choroidal arteries. However, persistence with a second and sometimes even third operation is recommended as 5-year survival rate of 84-97% can be achieved.[4,7] Postoperative subdural collections after transcortical tumor excision may occur, and may result from a persistent ventriculosubdural fistula, which may require subdural-peritoneal shunting.[5]

Malignant degeneration is rare. There is no role for chemotherapy or radiation for these WHO grade 1 lesions.

42.2.2 Atypical choroid plexus papilloma (atypical CPP) (WHO grade 2)

General information

Atypical CPP is a CPP (p. 739) having more mitotic figures than CPP (≥ 2 mitoses per 10 randomly selected HPFs) without frank signs of malignancy seen in choroid plexus carcinoma.[8] They are more likely to recur than their grade 1 counterpart.

Diagnostic criteria for atypical choroid plexus papilloma

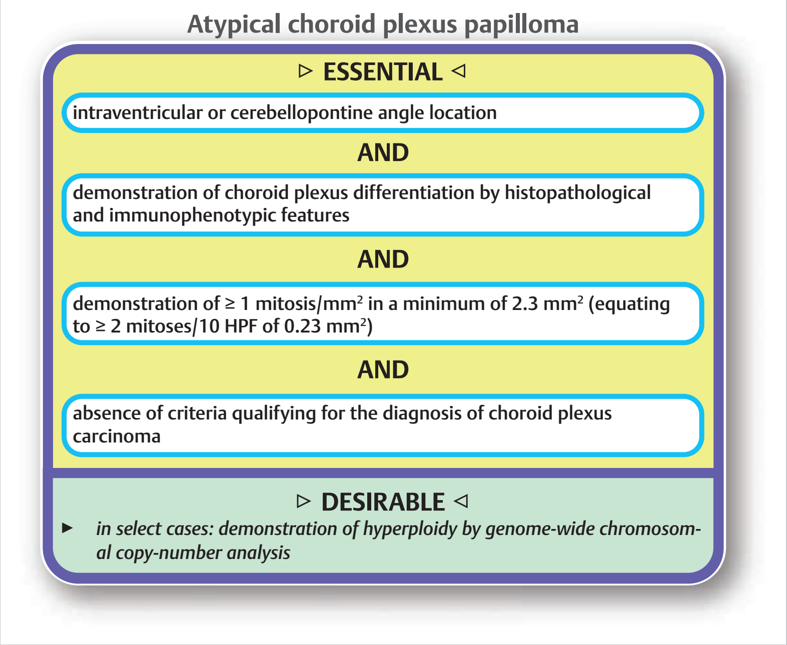
Diagnostic criteria for atypical choroid plexus papilloma are shown in ▶ Fig. 42.2.[3]

Location

Unlike CPP which occur equally as ofter supratentorially as infratentorially, these grade 2 lesions are more common in the lateral ventricles. See Intraventricular lesions (p. 1667) for differential diagnosis.

Epidemiology

Median age at diagnosis is younger than CPP (8-10 months vs. 26-35 months). All of the atypical CPP patients were < 10-11 years of age.



Atypical choroid plexus papilloma

▷ **ESSENTIAL** ◁

intraventricular or cerebellopontine angle location

AND

demonstration of choroid plexus differentiation by histopathological and immunophenotypic features

AND

demonstration of ≥ 1 mitosis/mm^2 in a minimum of 2.3 mm^2 (equating to ≥ 2 mitoses/10 HPF of 0.23 mm^2)

AND

absence of criteria qualifying for the diagnosis of choroid plexus carcinoma

▷ **DESIRABLE** ◁

- *in select cases: demonstration of hyperploidy by genome-wide chromosomal copy-number analysis*

Fig. 42.2 Diagnostic criteria for atypical choroid plexus papilloma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Imaging

Imaging appears the same as imaging with CPP (p. 740).

Prognosis

Prognosis is intermediate between CPP (grade 1) and choroid plexus carcinoma (grade 3). The definitional requirement of mitotic counts ≥ 2 per 10 HPF increased the 5-year recurrrence for atypical CPP by a factor of 5 over CPP.

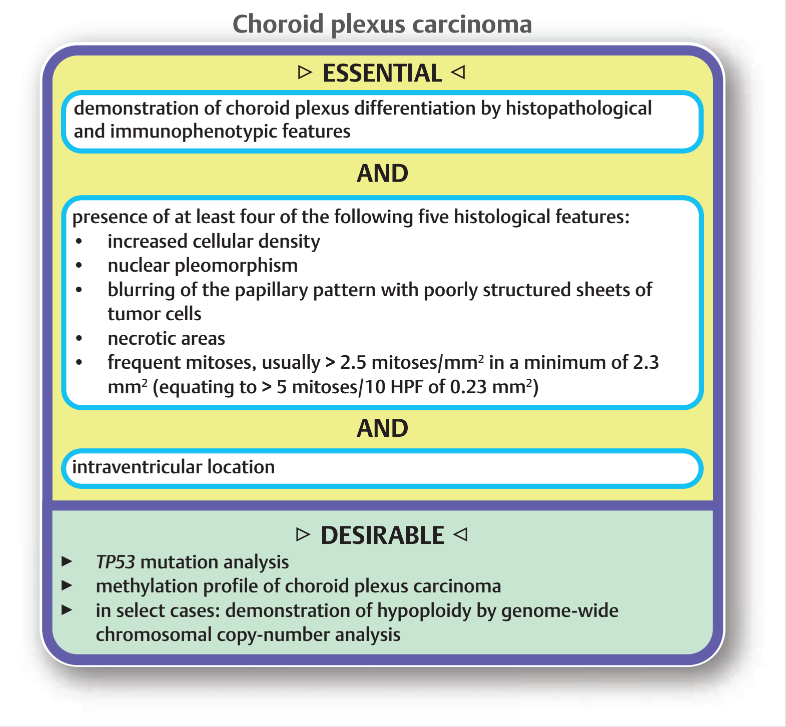
42.2.3 Choroid plexus carcinoma (CPC) (WHO grade 3)

General information

A malignant (WHO grade 3) tumor of the choroid plexus that invades adjacent brain and is prone to metastasize through the CSF (present in 21% at diagnosis). Occurs primarily in the lateral ventricles of children.

Diagnostic criteria for choroid plexus carcinoma

Diagnostic criteria for choroid plexus carcinoma are shown in ▶ Fig. 42.3.[3]



Choroid plexus carcinoma

▷ ESSENTIAL ◁

demonstration of choroid plexus differentiation by histopathological and immunophenotypic features

AND

presence of at least four of the following five histological features:

- increased cellular density
- nuclear pleomorphism
- blurring of the papillary pattern with poorly structured sheets of tumor cells
- necrotic areas
- frequent mitoses, usually > 2.5 mitoses/mm^2 in a minimum of 2.3 mm^2 (equating to > 5 mitoses/10 HPF of 0.23 mm^2)

AND

intraventricular location

▷ DESIRABLE ◁

- ▶ *TP53* mutation analysis
- ▶ methylation profile of choroid plexus carcinoma
- ▶ in select cases: demonstration of hypoploidy by genome-wide chromosomal copy-number analysis

Fig. 42.3 Diagnostic criteria for choroid plexus carcinoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Epidemiology

80% of all CPCs are foud in children.

Most arise sporadically, but, since 40% occur as part of Li-Fraumeni syndrome (p. 650) with germline *TP53* pathogenic sequence variants, genetic counselling and TP53 testing is recommended for all patients and their family.[3]

Imaging

CPCs have heterogeneous signal on T1 & T2 MRI, irregular enhancing margins (suggesting subependymal invasion), edema in the adjacent brain, vascular flow voids in 55%, and often present with hydrocephalus and early CSF dissemination.[9] Imaging of the entire neuraxis is recommended due to the high incidence of drop mets.

Treatment

Even malignant choroid plexus tumors respond to surgery.

Chemotherapy benefits a subset of patients.[10]

XRT was not shown to improve survival in patients undergoing surgery.

Prognosis

3- and 5-year progression free survival rates are 58% and 38% respectively, and overall survival is 83% and 62% for the same time periods.[11]

Absence of TP53 mutation may be associated with a more favorable outcome.

43 Embryonal Tumors

43.1 General information for embryonal tumors

Embryonal tumors are a diverse category of malignancies featuring immature tumor cells that resemble neural progenitors. It is divided into medulloblastomas (relatively common, occurring ≈ exclusively in the posterior fossa) and “other” rare non medulloblastoma CNS embryonal tumors (p. 754), many of which exhibit amplification of the C19MC region of chromosome 19.

Many of these tumors were formerly encompassed by the term primitive neuroectodermal tumor (PNET) which has been eliminated from the diagnostic lexicon.[1]

43.2 Medulloblastoma (a subset of embryonal tumors), general aspects

43.2.1 General information

Key concepts

- a small-cell embryonal WHO grade 4 neuroepithelial tumor that occurs predominantly in the posterior fossa of children (peak: 1st decade). The most common pediatric brain malignancy
- classified on 4 molecular and 4 histologic criteria
  - 4 molecularly defined types: 1) WNT-activated; 2) SHH-activated (TP53-mutant & -wildtype); 3) non-WNT/non-SHH, group 3; 4) non-WNT/non-SHH, group 4
  - 4 histologic types: 1) classic; 2) desmoplastic/nodular (D/N); 3) extensive nodularity (MBEN); 4) large cell/anaplastic (LC/A)
- brainstem invasion usually limits complete surgical excision
- staging: all patients must be evaluated for “drop mets” (imaging the entire neuraxis with contrast - brain + spine, pre-operatively if possible), and postoperatively with LP for CSF cytology

Medulloblastomas (MDB) are WHO grade 4 embryonal neuroepithelial tumors that typically occur in the posterior fossa (cerebellum or dorsal brainstem) of children. In the cerebellum, they typically arise in the vermis near the apex of the roof of the 4th ventricle (the fastigium [Latin for summit]). They acount for 68% of embryonal tumors.[2]

43.2.2 Seeding and metastases

≈ 10–35% have seeded the craniospinal axis at the time of diagnosis,[3] and extraneural mets occur in 5% of patients,[4] sometimes promoted by shunting[5] (although this is uncommon[6]).

43.2.3 Clinical

Clinical history is typically brief (6–12 weeks). Predilection for posterior fossa predisposes to early obstructive hydrocephalus. Usual presenting symptoms: H/A, N/V, and ataxia. Infants with hydrocephalus may present with irritability, lethargy, or progressive macrocrania.[7] Spinal drop mets may produce back pain, urinary retention, or leg weakness.

Common signs: papilledema, truncal and appendicular ataxia, nystagmus, EOM palsies. Macrocrania in infants and young children.

43.2.4 Classification

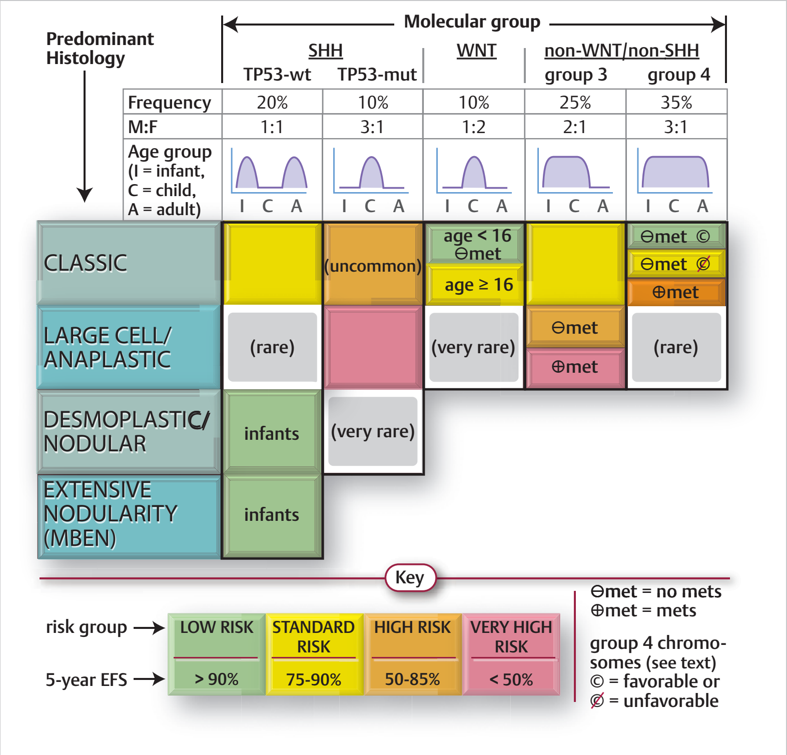
Classification of medulloblastomas based on a combination of molecular signatures combined with histopathological findings is recommended and provides optimal prognostic information. Molecularly defined MDBs are associated with specific morphological patterns to a high degree.

Molecular genetics: Transcriptome profiling (analysis of all RNA in a cell population), microRNA analysis and methylome profiling allows MDBs to be segregated into these 4 principal types[8] (which are covered individually in the following sections). NB: on a more granular level, additional subgroups have been identified and will continue to emerge.

1. WNT-activated (p. 750)
2. SHH-activated
    a) SHH-activated, TP53-wildtype (p. 751)
    b) SHH-activated, TP53-mutant (p. 752)
3. non-WNT/non-SHH (p. 753), group 3
4. non-WNT/non-SHH (p. 753), group 4

Histology: 4 histologic types are defined; see detailed descrition (p. 749)
1. classic (p. 749)
2. desmoplastic/nodular (p. 749) (D/N MDB)
3. extensive nodularity (p. 749) (MBEN)
4. large cell/anaplastic (p. 749) (LC/A MDB)

The distribution and prognosis of the histologic variants and prognostic information among the molecularly classified MDBs is depicted graphically in ▶ Fig. 43.1 (this is not the entire gamut, see reference[9] for more details).



Predominant Histology	Molecular group: SHH TP53-wt	SHH TP53-mut	WNT	non-WNT/non-SHH group 3	non-WNT/non-SHH group 4

5-year EFS rates: **low risk** > 90%, **standard risk** 75-90%, **high risk** 50-75%, **very high risk** < 50%
(see text for more details).[8,10,11] No risk is shown for tumors of uncertain clinicopathological significance.
Abbreviations: EFS = event-free survival; MDB = medulloblastoma; SHH = activated sonic hedgehog; TP53 = tumor protein 53; mut = mutant; wt = wildtype; WNT = activated wingless/integrated (signal transduction pathway).
© = favorable chromosomal findings for non-WNT/non-SHH group 4: chromosome 7 gain, chromosome 8 loss, chromosome 11 loss, chromosome 17 gain.

43.2.5 Evaluation

MDBs usually appear as a solid, IV-contrast-enhancing lesion on CT or MRI. Most are located in the midline in the region of the 4th ventricle (laterally situated tumors are more common in adults). Most have hydrocephalus at the time of presentation. Ependymoma (p. 1647) is the main entity from which to differentiate on imaging. MDBs tend to protrude into the 4th ventricle from the posterior aspect (the “roof”) of the ventricle, whereas ependymomas more commonly arise from the floor.

CT: noncontrast → typically hyperdense (due to high cellularity). Contrast → most enhance. 20% have calcifications. CT has poor resolution in the posterior fossa due to bone interference

MRI: Can be variabled (▶ Fig. 43.2). T1WI → hypo- to isointense. T2WI → heterogeneous due to tumor cysts, vessels, and calcifications.[12] Most enhance. **MRS:** elevated choline and decreased NAA.

Spinal imaging: MRI with IV gadolinium or CT/myelography with water-soluble contrast should be done to rule out “drop mets.” Staging is done either pre-op or within 2–3 weeks of surgery.

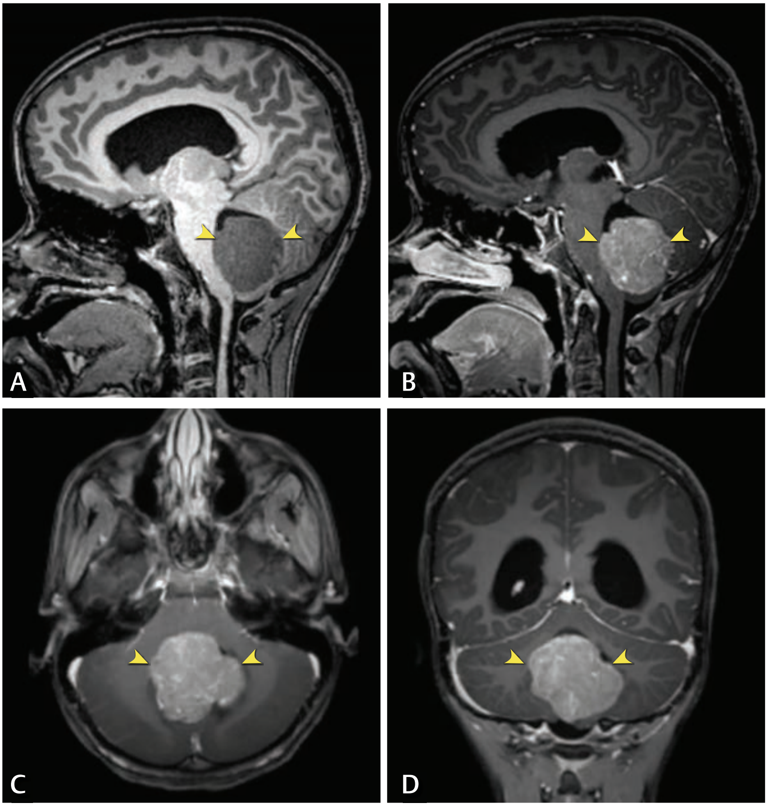

Fig. 43.2 Medulloblastoma. MRI of 10-year-old patient with medulloblastoma (*yellow arrowheads*) in the 4th ventricle producing obstructive hydrocephalus, presenting with progressive H/A, nausea and acute emesis. Image: A: sagittal T1 FLAIR without contrast, B: sagittal T1 FLAIR with contrast, C: axial T1 with contrast, D: coronal T1 with contrast.

▶ **Staging.** Staging employs MRI of the entire neuraxis without and with contrast and, postoperatively, CSF cytology obtained by LP. The grading system of Chang et al. (▶ Table 43.1) is still used.

Table 43.1 Post-operative staging system for medulloblastoma[13]

Stage	Description
M0	no metastasis
M1	microscopic tumor cells in the CSF
M2	gross nodular seeding in the cerebellar/cerebral subarachnoid space or in the third or lateral ventricles
M3	gross nodular seeding in the spinal subarachnoid space
M4	metastasis outside the CNS

43.2.6 Treatment

Surgical intervention

Surgical debulking of as much tumor as possible (without causing neurological injury) to obtain tissue for classification and to improve outcome is considered standard.

Invasion of or attachment to the floor of the fourth ventricle (brainstem in the region of the facial colliculus) often limits excision. It is better to leave a small residual on the brainstem (these patients do fairly well) than it is to chase every last remnant into the brainstem (neurologic deficit is more likely with this).

Surgical exposure of midline cerebellar medulloblastomas requires opening of the foramen magnum, usually removal of the posterior arch of C1, and occasionally the arch of C2. Tumor spread with arachnoidal thickening ("sugar coating") may occur.

Shunts: 30–40% of children require permanent VP shunts following p-fossa resection. The risk of shunt-related seeding has been quoted as high as 10–20%,[3] but this is probably overestimated.[6] In the past, tumor filters were sometimes used. They are less commonly used today because of the high incidence of obstruction.

Post-op adjuvant therapy

Following surgery, stratification of patients into risk groups guides subsequent therapy. One postoperative stratification scheme is shown in ▶ Table 43.2. Other systems have been published e.g., for pediatrics (age 3–17 years).[8]

In children: chemotherapy can be used to delay the need for XRT in 20–40% of children < 3–4 years of age with non-disseminated MBD.[15]

▶ **Low-risk and standard-risk patients**

- especially in pediatrics, may consider reduced dose XRT: 23.4 Gy with a boost to the primary site of 54–55.8 Gy with adjuvant chemotherapy
- or conventional fractionated XRT (see high-risk below)

▶ **High- and very high-risk patients**

- conventional fractionated XRT (once a day) for 54 Gy to the primary tumor and 18 Gy to the craniospinal axis
- chemotherapy[15]
  - agents that have been used include: cisplatin, lomustine, vincristine, cyclophosphamide, etoposide, simultaneous high-dose IV methotrexate and/or intrathecal methotrexate of mafosfamide, and/or intraventricular methotrexate
  - in adults: SHH-activated MDBs (which have higher prevalence of PTCH & SMO mutations) may be more responsive to SMO receptor inhibitors and SHH-inhibiting drugs such as vismodegib[15]

43.2.7 Prognosis

Prognostic details for specific tumor types will be found in the following sections. Poor prognosticators in general include[16]:

- in some cell types younger age (especially if < 3 yrs). For other cell types (e.g., desmoplastic/nodular or MBEN, the prognosis for infants is favorable)
- disseminated (metastatic) disease at the time of diagnosis except for MBEN
- inability to perform gross-total removal (especially if residual > 1.5 cm^2 with localized disease)
- poor Karnofsky performance scale score (p. 1640)

Most common site of recurrence is p-fossa.

Table 43.2 Postoperative risk stratification in medulloblastoma[14,15,11]

Standard-risk tumors

- total or near total surgical resection[a]
- no CNS metastases on MRI of brain and spine
- no tumor cells on cytospin of lumbar CSF
- no clinical evidence of extra-CNS metastases
- MDB classification
  - SHH-activated, TP53-wildtype with classic histology
  - or non-WNT/non-SHH, group 4, with classic histology and no metastases at diagnosis and no favorable chromosomal findings[b]
  - or non-WNT/non-SHH, group 3
  - or WNT with classic histology age ≥ 16 years

Low-risk tumors

- MDB classification
  - WNT-activated group
    - β-catenin mutation (mandatory testing)
    - β-catenin nuclear immunopositivity by immuno-histochemistry & monosomy 6 (optional testing)
  - or SHH-activated, TP53-wildtype in infants with
    - desmoplastic/nodular histology
    - or extensive nodularity histology
- total or near total surgical resection[a]

High-risk tumors

- large cell/anaplastic histology non-WNT/non-SHH, group 3 without metastases at diagnosis
- classic histology with
  - SHH-activated, TP53-mutant
  - or non-WNT/non-SHH, group 4 with metastases at diagnosis
- unresectable tumor or residual tumor $> 1.5\ \text{cm}^2$ on axial-plane early post-op MRI
- extra-CNS metastases

Very high-risk tumors

- large cell/anaplastic histology with
  - SHH-activated, TP53-mutant
  - or non-WNT/non-SHH, group 3 with metastases at diagnosis

[a] near total resection: $< 1.5\ \text{cm}^2$ on axial-plane early post-op MRI. This criteria is controversial as much of the data is from CT era[8]

[b] favorable chromosomal findings for non-WNT/non-SHH group 4: chromosome 7 gain, chromosome 8 loss, chromosome 11 loss, and chromosome 17 gain

Long-term survivors of MDB are at significant risk for permanent endocrinologic, cognitive, and psychological sequelae of treatments. Infants and very young children with MDB remain a difficult therapeutic challenge because they have the most virulent form of the disease and are at highest risk for treatment-related sequelae.

43.3 Medulloblastomas by definition criteria

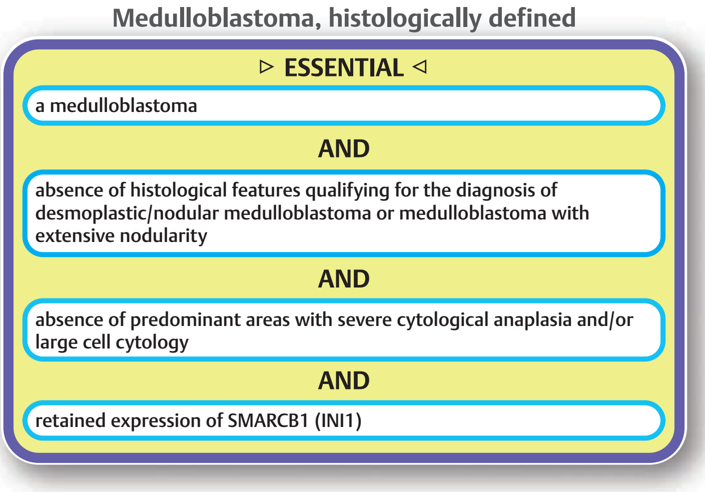
43.3.1 Medulloblastoma, histologically defined

General information

An embryonal neuroepithelial tumor that occurs in the posterior fossa consisting of small, poorly differentiated cells with a high nuclear to cytoplasmic ratio with profuse mitotic activity and apoptosis. Divided into 4 histologic subtypes described below. On the rare occasion that any subtype shows myogenic and/or melanocytic differentiation, the terms “medullomyoblastoma” and “melanocytic medulloblastoma” respectively may be used in the description.

Diagnostic criteria for medulloblastoma, histologically defined

Diagnostic criteria for medulloblastoma, histologically defined are shown in ▶ Fig. 43.3.[9]



Medulloblastoma, histologically defined

▷ ESSENTIAL ◁

a medulloblastoma

AND

absence of histological features qualifying for the diagnosis of desmoplastic/nodular medulloblastoma or medulloblastoma with extensive nodularity

AND

absence of predominant areas with severe cytological anaplasia and/or large cell cytology

AND

retained expression of SMARCB1 (INI1)

Fig. 43.3 Diagnostic criteria for medulloblastoma, histologically defined. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Subtypes (histologic/morphologic variants)

- **MDB, classic:** densely packed undifferentiated small round cells with mild-to-moderate nuclear pleomorphism and high mitotic count. Comprise ≈ 72% of MDBs. Occur at any age, but predominate in childhood. Found in all 4 molecular MDB types.
- **desmoplastic/nodular MDB:** nodular, reticulin-free zones and intervening densely packed, poorly differentiated cells in an intercellular network of reticulin-positive collagen fibers. Account for ≈ 20% of all MDBs. Occurs in cerebellar hemispheres and midline. Bimodal age distribution: 1) young children and adolescents, 2) adults. Associated with Gorlin syndrome in early childhood. The prognosis in early childhood is excellent with surgery + chemotherapy alone, and is likely better than with any other histologic subtype.
- **MDB with extensive nodularity** (MBEN): numerous reticulin-free neurocytic nodules with a neuropil matrix and narrow internodular strands of poorly differentiated tumor cells in a desmoplastic matrix. Occurs primarily in infants. Accounts for < 5% of MDBs overall, but up to 50% of cases in age < 3 years. Outcome is favorable with near 100% 5-year OS in many (but not all) series. > 80% of these occur in the vermis. The presence of metastases at diagnosis in this group does not affect prognosis.
- **large cell/anaplastic MDB:** Undifferentiated cells with marked nuclear pleomorphism, prominent nucleoli, and hight mitotic and apoptotic counts. Accounts for 10% of MDBs. Found in all 4 molecular MDB types. The LC/A morphology is an independent prognosticator of poor outcome (5-year PFS is 30-40%) (very high-risk MDB) justifying aggressive adjuvant therapy. Molecular biology of MDB SHH-activated TP53-mut and non-WNT/non-SHH group 3 with MYC amplification can behave more aggressively.

Staging

See postoperative staging (p. 746).

Treatment

For treatment, see treatment for medulloblastomas (p. 747).

43.3.2 Medulloblastomas, molecularly defined

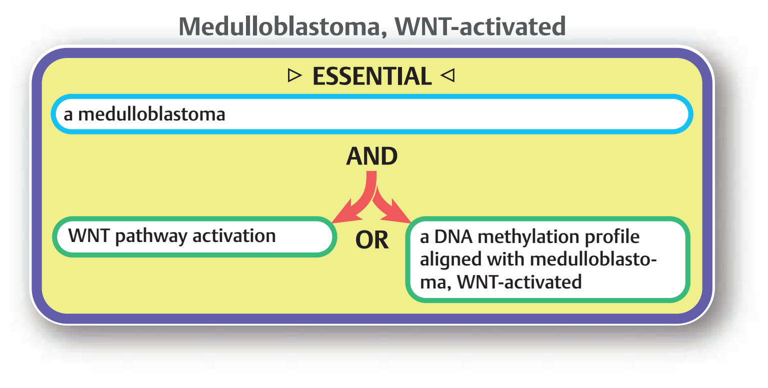
Medulloblastoma, WNT-activated (WHO grade 4)

General information

Typical in older childhood (hardly ever in infancy). Account for ≈ 10% of all MDBs and ≈ 15% of adult MDBs. Male:female = 1:2. Predominant histologic variant: classic (almost all). Favors the cerebellar midline. Putative cell of origin: lower rhombic lip progenitor cells. Frequent genetic mutations: CTNNB1, DDX3X, TP53.

Diagnostic criteria for medulloblastoma, WNT-activated

Diagnostic criteria for medulloblastoma, WNT-activated are shown in ▶ Fig. 43.4.[9]



Medulloblastoma, WNT-activated
▷ ESSENTIAL ◁
a medulloblastoma
AND
WNT pathway activation
OR
a DNA methylation profile aligned with medulloblastoma, WNT-activated

Fig. 43.4 Diagnostic criteria for medulloblastoma, WNT-activated. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Location

Generally either of the following:

- around the foramen of Luschka, arising from the brainstem or cerebellum
- or in the cerebellar midline, generally contiguous with the brainstem

Extension towards the CPA or cerebellar peduncle occurs in a significant number.

Histology

See section 43.3.1.

▶ **Classic morphology.** Almost all WNT-activated MDBs have classic morphology.

▶ **Large cell/anaplastic morphology.** Very rare. Uncertain clinical significance.

Staging

See postoperative staging (p. 746).

Treatment

For treatment, see treatment for medulloblastomas (p. 747).

Prognosis

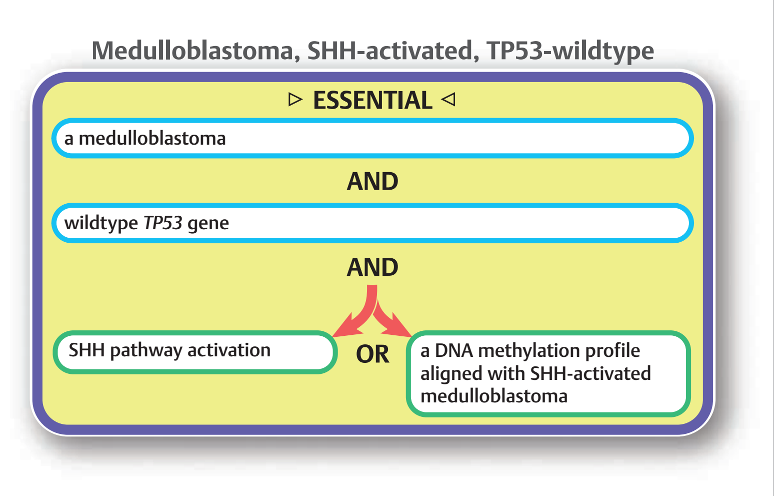
In spite of being a grade 4 neoplasm, the prognosis for children is excellent with surgery and adjuvant therapy. In contrast, the prognosis is poor for adults.

Medulloblastoma, SHH-activated, TP53-wildtype (WHO grade 4)

Typical in infancy and adult. Male:female = 1:1. Predominant histologic variant: desmoplastic/nodular. Putative cell of origin: cerebellar granule neuron cell precursors of the external granule cell layer and cochlear nucleus; less likely neural stem cells of the subventricular zone. Frequent genetic mutations: PTCH1, SMO (adults), SUFU (infants), TERT promoter.

Diagnostic criteria for medulloblastoma, SHH-activated, TP53-wildtype

Diagnostic criteria for medulloblastoma, SHH-activated, TP53-wildtype are shown in ▶ Fig. 43.5.[9]



Medulloblastoma, SHH-activated, TP53-wildtype
▷ ESSENTIAL ◁
a medulloblastoma
AND
wildtype *TP53* gene
AND
SHH pathway activation
OR
a DNA methylation profile aligned with SHH-activated medulloblastoma

Fig. 43.5 Diagnostic criteria for medulloblastoma, SHH-activated, TP53-wildtype. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Subtypes

See reference.[9]

Four provisional molecular subgroups are determined by DNA methylation or transcriptome profiling

- **SHH-1**
- **SHH-2**
- **SHH-3**
- **SHH-4**

Location

Infants: the cerebellar vermis is much more frequently than the cerebellar hemispheres.

Older children and young adults: mainly involves the hemispheres.

Epidemiology

SHH activated meduloblastomas exhibit a bimodal age distribution with one peak in infants and the other in adults. M:F ratio is ≈ 1.5:1.

Histology

See section 43.3.1.

Most MDB, SHH activated TP53-wt tumors are desmoplastic/nodular or MBENS.

▶ **Classic morphology.** Prognosis: Standard risk tumor.

- **Large cell/anaplastic morphology.** Rare. Uncertain clinical significance.
- **Desmoplastic/nodular morphology.** Prognosis: low risk tumor. Prevalent in infants and adults.
- **Extensive nodularity morphology** (MBEN). Prognosis: low risk tumor. Prevalent in infants.

Staging

See postoperative staging (p. 746).

Treatment

For treatment, see treatment for medulloblastomas (p. 747).

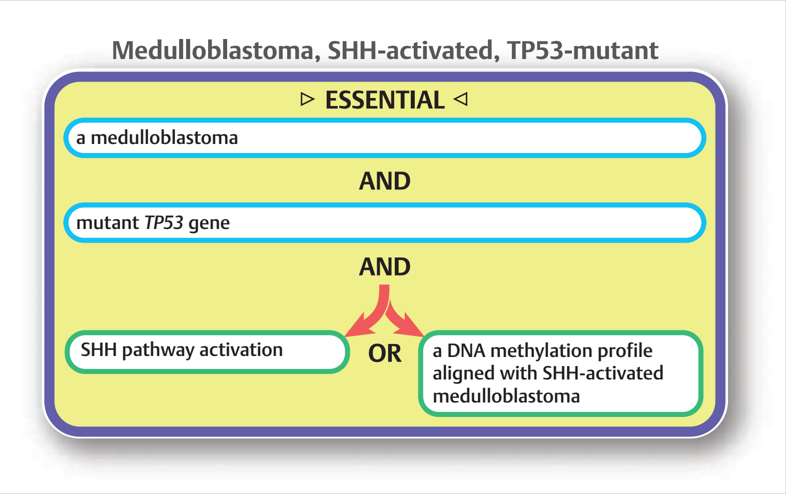
Medulloblastoma, SHH-activated, TP53-mutant (WHO grade 4)

General information

Typical in childhood. Male:female = 1:1. Predominant histologic variant: large cell/anaplastic. Putative cell of origin: cerebellar granule neuron cell precursors of the external granule cell layer and cochlear nucleus; less likely neural stem cells of the subventricular zone.

Diagnostic criteria for medulloblastoma, SHH-activated, TP53-mutant

Diagnostic criteria for medulloblastoma, SHH-activated, TP53-mutant are shown in ► Fig. 43.6.[9]



Medulloblastoma, SHH-activated, TP53-mutant
▷ ESSENTIAL ◁
a medulloblastoma
AND
mutant *TP53* gene
AND
SHH pathway activation
OR
a DNA methylation profile aligned with SHH-activated medulloblastoma

Fig. 43.6 Diagnostic criteria for medulloblastoma, SHH-activated, TP53-mutant. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Subtypes

The same four subtypes as MDB SHH-activated TP53-wildtype (viz. SHH 1-4).

Histology

See section 43.3.1.

Metastatic disease and MYCN amplification are independent poor prognosticators in children (not infants) and adolescents.

- **Classic morphology.** Prognosis: high-risk tumor. Uncommon.

- **Large cell/anaplastic morphology.** The predominant histologic type (70%). Prognosis: high-risk tumor. Prevalent in ages 7–17 years.

- **Desmoplastic/nodular morphology.** Very rare. Uncertain clinical significance.

Staging

See postoperative staging (p. 746).

Treatment

For treatment, see treatment for medulloblastomas (p. 747).

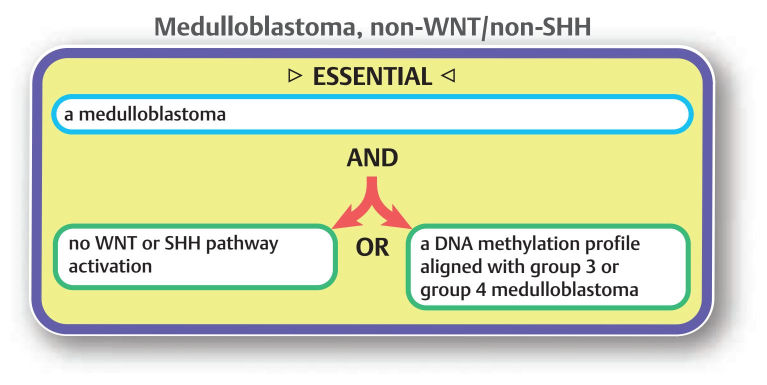
Medulloblastoma, non-WNT/non-SHH (WHO grade 4)

General information

An embryonal tumor of the cerebellum without a molecular signature. Classified as group 3 or group 4 tumors, with 8 molecular subgroups as determined by DNA methylation profiling. Typical in infancy and childhood. Male:female = 2:1. They occur exclusively in the inferior cerebellum, usually near the midline. Predominant histologic variants: classic; large cell/anaplastic. Putative cell of origin: cerebellar granule neuron cell precursors of the external granule cell layer. Frequent genetic mutations: PVT1-MYC, GFI1/GFI1B structural variants.

Diagnostic criteria for medulloblastoma, non-WNT/non-SHH

Diagnostic criteria for medulloblastoma, non-WNT/non-SHH are shown in ▶ Fig. 43.7.[9]



Medulloblastoma, non-WNT/non-SHH
▷ ESSENTIAL ◁
a medulloblastoma
AND
no WNT or SHH pathway activation
OR
a DNA methylation profile aligned with group 3 or group 4 medulloblastoma

Fig. 43.7 Diagnostic criteria for medulloblastoma, non-WNT/non-SHH. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Subtypes

There are 8 subgroups of group 3/4 as differentiated by DNA methylation profiling.

Histology

See section 43.3.1.

- **Classic morphology.** The most common histology for this tumor. Prognosis: Standard risk tumor.

▸ **Large cell/anaplastic morphology.** This histology is more prevalent in group 3 than group 4. Prognosis: high risk tumor.

Staging

See postoperative staging (p. 746).

Treatment

For treatment, see treatment for medulloblastomas (p. 747).

Prognosis

In group 3 MDBs, MYC amplification is associated with poor outcome, but other markers also have prognostic impact.

Among group 4 MDBs, metastatic disease at the time of diagnosis is the strongest indicator of poor outcome. Favorable outcome in group 4 is associated with chromosome 7 gain, chromosome 8 loss, chromosome 11 loss, and chromosome 17 gain.

43.4 CNS embryonal tumors other than medulloblastoma

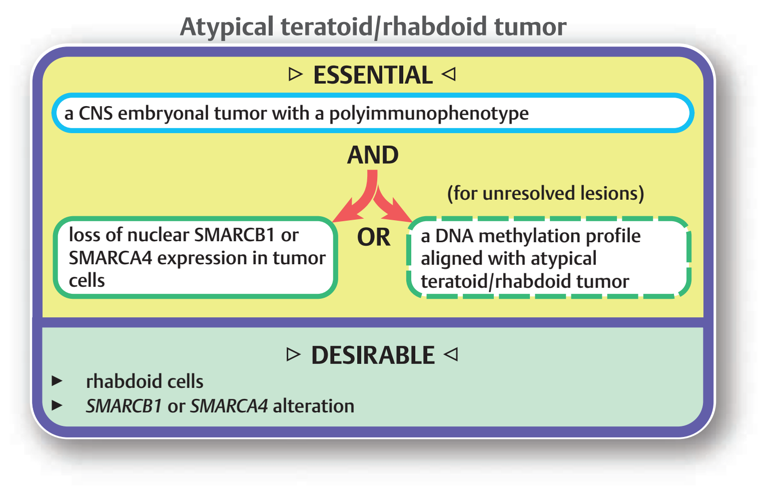
43.4.1 Atypical teratoid/rhabdoid tumor (AT/RT) (WHO grade 4)

General information

A high-grade malignant WHO grade 4 embryonal tumor of the CNS comprised of poorly differentiated elements and rhabdoid cells which exhibit biallelic inactivation of *SMARCB1* or rarely *SMARCA4* and which can differentiate along neuroepithelial, epithelial and mesenchymal cell lines. Many of these tumors were probably previously misdiagnosed as MDBs.

Diagnostic criteria for atypical teratoid/rhabdoid tumor

Diagnostic criteria for atypical teratoid/rhabdoid tumor are shown in ▸ Fig. 43.8.[9]



Atypical teratoid/rhabdoid tumor
▷ ESSENTIAL ◁
a CNS embryonal tumor with a polyimmunophenotype
AND
(for unresolved lesions)
loss of nuclear SMARCB1 or SMARCA4 expression in tumor cells
OR
a DNA methylation profile aligned with atypical teratoid/rhabdoid tumor
▷ DESIRABLE ◁
▸ rhabdoid cells
▸ *SMARCB1* or *SMARCA4* alteration

Fig. 43.8 Diagnostic criteria for atypical teratoid/rhabdoid tumor. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Subtypes

Three molecular subtypes are identifiable on DNA methylation profiling:

- **AT/RT-SHH**
- **AT/RT-TYR**
- **AT/RT-MYC**

Location

Anywhere along the neuraxis. Supratentorial location is more likely with advancing age, and includes the hemispheres, and less often the ventricles, or suprasellar or pineal region. Other locations include cerebellar hemispheres, cerebellopontine angle and brainstem. Spinal cord involvement is rare. 33% have CSF spread at presentation.

Epidemiology

Occurs primarily in infants and children (most are age < 2 years, 33% are ≤ 1 year old, and > 90% are < 5 years). Rare in adults. AT/RT account for 17% of embryonal tumors.[2]

Familial cases may occur in cohorts with rhabdoid tumor predisposition syndrome.

Staging

See postoperative staging (p. 746).

Prognosis

Althogh the prognosis is poor, not all AT/RTs have the same behavior. Pending validation studies, prognosis may be predicted based on molecular group, age, location and extent of resection.

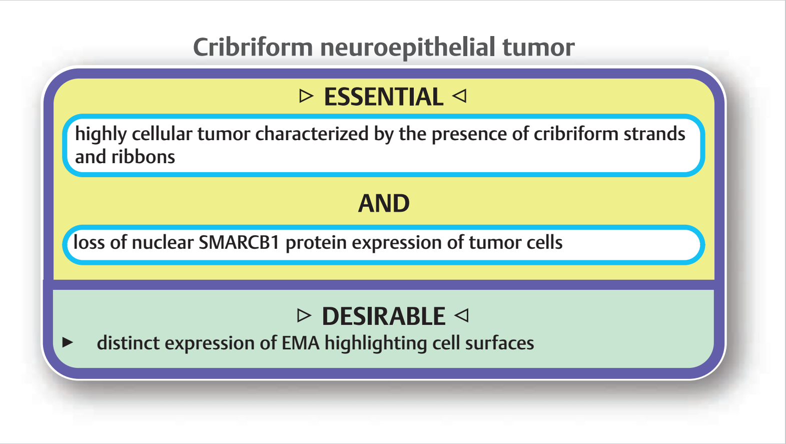
43.4.2 Cribriform neuroepithelial tumor (CRINET) *(provisional)*

General information

A *provisional* non-rhabdoid neuroectodermal neoplasm identifiable by cribriform strands and ribbons with loss of SMARCB1 expression.

Diagnostic criteria for cribriform neuroepithelial tumor

Diagnostic criteria for cribriform neuroepithelial tumor are shown in ▶ Fig. 43.9.[9]



Cribriform neuroepithelial tumor

▷ ESSENTIAL ◁

highly cellular tumor characterized by the presence of cribriform strands and ribbons

AND

loss of nuclear SMARCB1 protein expression of tumor cells

▷ DESIRABLE ◁

▶ distinct expression of EMA highlighting cell surfaces

Fig. 43.9 Diagnostic criteria for cribriform neuroepithelial tumor. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Location

Near any of the ventricles (3rd, 4th, or lateral).

Epidemiology

Median age: 20 months (range: 10-129 months). M:F ratio 1.5:1.[17]

Prognosis

In 10 patients with CRINET, estimated mean OS was 125 months.[17]

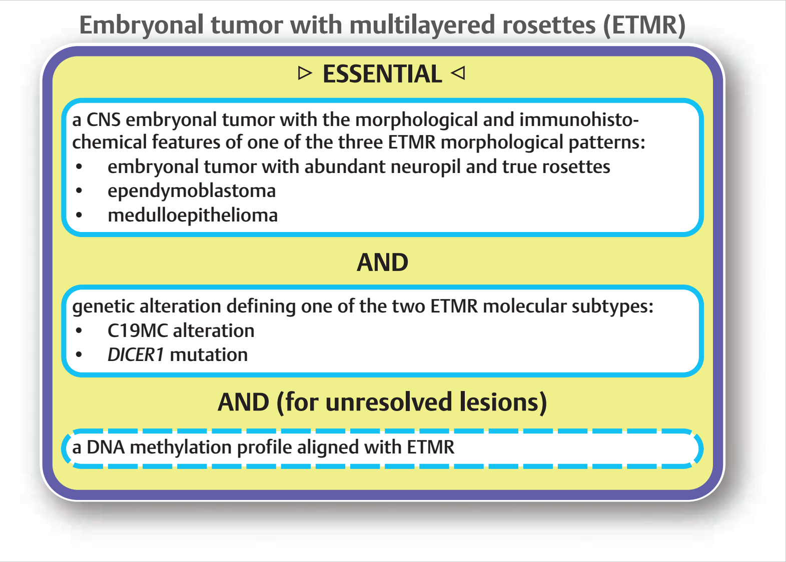
43.4.3 Embryonal tumor with multilayered rosettes (ETMR) (WHO grade 4)

General information

A WHO grade 4 embryonal tumor with multilayered rosettes demonstrating one of three histological patterns (embryonal tumor with abundant neuropil and true rosettes, ependymoblastoma, or medulloepithelioma) typically exhibiting amplification in the C19MC region on chromosome 19 (19q13.42) or, rarely, a *DICER1* mutation. May develop in the cerebrum, brainstem, or cerebellum. Usually affect children < 4 years old (with the vast majority being < 2 years old).

Diagnostic criteria for embryonal tumor with multilayered rosettes

Diagnostic criteria for embryonal tumor with multilayered rosettes are shown in ▶ Fig. 43.10.[9]



Embryonal tumor with multilayered rosettes (ETMR)

▷ ESSENTIAL ◁

a CNS embryonal tumor with the morphological and immunohistochemical features of one of the three ETMR morphological patterns:

- embryonal tumor with abundant neuropil and true rosettes
- ependymoblastoma
- medulloepithelioma

AND

genetic alteration defining one of the two ETMR molecular subtypes:

- C19MC alteration
- *DICER1* mutation

AND (for unresolved lesions)

a DNA methylation profile aligned with ETMR

Fig. 43.10 Diagnostic criteria for embryonal tumor with multilayered rosettes. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Subtypes

- **embryonal tumor with multilayered rosettes, C19MC-altered**
- **embryonal tumor with multilayered rosettes, *DICER1*-mutated**

Location

The cerebral hemispheres is the most common location, with 45% located elsewhere including the posterior fossa. Spinal cord involvement is rare.

Epidemiology

Data is sparse due to the rarity of the tumor. Primarily affects children < 4 years, with most younger than 2. M:F ratio is close to 1:1.

Staging

See postoperative staging (p. 746).

Prognosis

These aggressive tumors grow rapidly producing precipitous clinical deterioration. Mean OS is 12 months following intensive treatment.[9] Outcome is worse when metastases are present at diagnosis and with brainstem involvement. Gross total resection, XRT and aggressive chemotherapy are “probably helpful.”

45 Cranial and Paraspinal Nerve Tumors

45.1 General information

These slow-growing tumors may occur sporadiaclly or as part of a syndromic condition such as neurofibromatosis (type 1 or type 2), schwannomatosis, and Carney complex (p.652). The WHO now considers paragangliomas which involve sympathetic and parasympathetic neuroendocrine cells to be grouped in this category in contrast to the historical classification as neuronal and mixed neuronal-glial tumors. Schwannomatosis may be associated with painful schwannomas.

45.2 Specific cranial and paraspinal nerve tumors

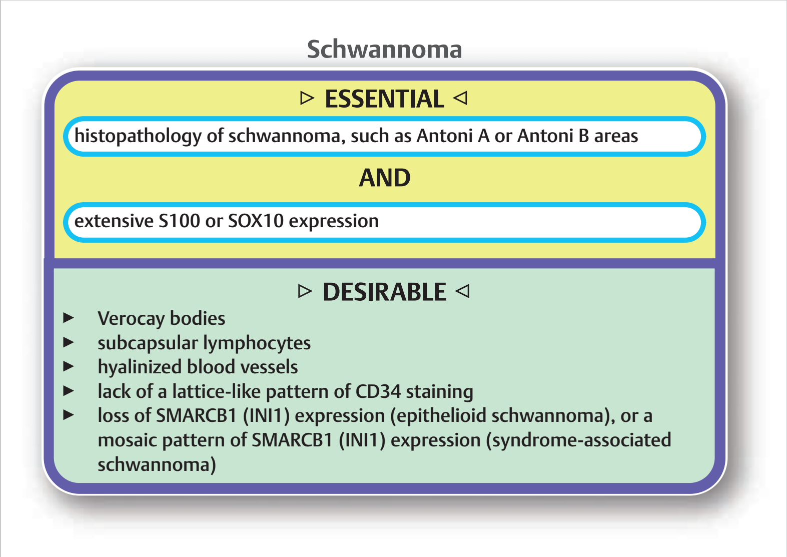
45.2.1 Schwannoma (WHO grade 1)

General information

A benign nerve sheath tumor exclusively or primarily comprised of differentiated neoplastic Schwann cells. May be sporadic or associated with syndromes. Over 90% are solitary and sporadic, and 50-75% of these show inactivating mutations of the NF2 suppressor gene located at 22q12.2 resulting in loss of expression of the growth inhibiting product, merlin (AKA schwannomin). Multiple schwannomas occur in NF2 (p.640) (bilateral involvement of the vestibular division of Cr N VIII is diagnostic of NF2) and schwannomatosis (p.642). Spinal schwannomas are typical in NF1 (p.638).

Diagnostic criteria for schwannoma

Diagnostic criteria for schwannoma are shown in ▶ Fig. 45.1.[1]



Schwannoma

▷ ESSENTIAL ◁

histopathology of schwannoma, such as Antoni A or Antoni B areas

AND

extensive S100 or SOX10 expression

▷ DESIRABLE ◁

- Verocay bodies
- subcapsular lymphocytes
- hyalinized blood vessels
- lack of a lattice-like pattern of CD34 staining
- loss of SMARCB1 (INI1) expression (epithelioid schwannoma), or a mosaic pattern of SMARCB1 (INI1) expression (syndrome-associated schwannoma)

Fig. 45.1 Diagnostic criteria for schwannoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Subtypes

See reference.[1]

- **ancient schwannoma**: contains dispersed cells with bizarre nuclei
- **cellular schwannoma**: Antoni A tissue predominates. Verocay bodies are absent. Small areas of necrosis may cause confusion with MPNST (p. 774). May contain foci of Ki-67 labeling (the index is usually < 20%, but not always)
- **plexiform schwannoma**: often arise in skin or sub-Q tissue. Most are sporadic, but may occur in HF2 or schwannomatosis. Histology may be classic (i.e., biphasic) or cellular subtype
- **epithelioid schwannoma**: demonstrate multilobulated single or nests of epithelioid cells in a myxoid or hyalinized matrix. Most are sporadic
- **microcystic/reticular schwannoma**: the least common subtype. Typically occur in viscera (usually the GI tract) where they are unencapsulated. Named for a rich microcystic network of spindle cells with eosiniphilic cytoplasm. Antoni A tissue is common, and they usualy lack features of hyalinized blood vessels and Verocay bodies

Location

Commonly arise from peripheral nerves in the skin and subcutaneous tissue of the head and neck, or on flexor surfaces of the limbs. Intracranially, they frequently involve the vestibular division of Cr. N. VIII (vestibular schwannoma (p. 777)), but can also arise from Cr. N. V or other cranial nerves. In the spine, they can form "dumbbell"-shaped tumors as they extend out through the neural foramen which constricts them.

Histology

Most are biphasic (composed of 2 cell types):

1. Antoni A tissue: compact. Occasional Verocay bodies (nuclear palisading)
2. Antoni B tissue: loosely arrayed with lipid-laden histiocytes and hyalinized vasculature.

Refer to the comparison of the histology to that of neurofibromas (p. 637).

Epidemiology

Peak incidence is the fourth to sixth decades.

Prognosis

The sporadic forms of these benign tumors usually do not recur following gross total resection. However, GTR is often difficult with the cellular and plexiform subtypes. Malignant transformation is exceedingly rare.

45.2.2 Neurofibroma (WHO grade 1)

General information

The most common peripheral nerve sheath tumor. A benign neoplasm composed of neoplastic Schwann cells interspersed with normal cells. They are WHO CNS5 grade 1 except for atypical neurofibromatous neoplasm of uncertain biological potential (ANNUBP), which is not assigned a grade. The finding of multiple or plexiform neurofibromas should prompt consideration of underlying NF1. Complete functional loss of neurofibromin (p. 639) is considered a prerequisite for tumor development. Refer to the comparison of the histology to that of schwannomas (p. 637).

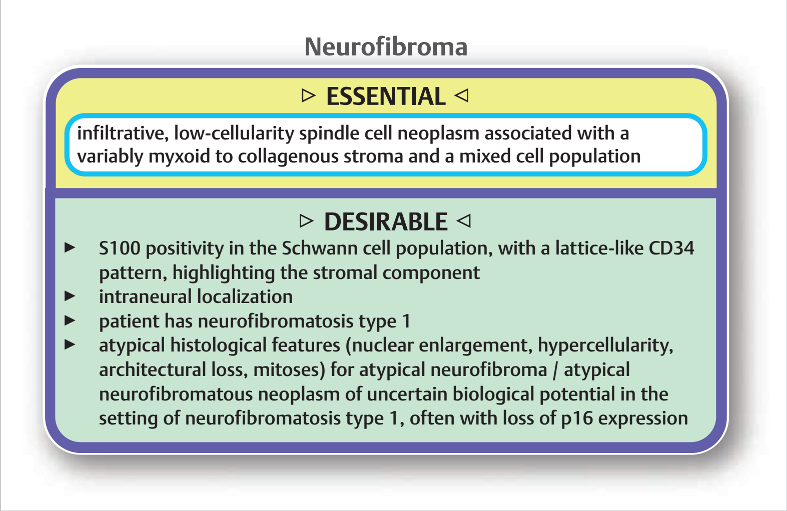
Diagnostic criteria for neurofibroma

Diagnostic criteria for neurofibroma are shown in ► Fig. 45.2.[1]

Subtypes

See reference.[1]

- **cellular neurofibroma**
- **atypical neurofibroma / neurofibromatous neoplasm of uncertain biological potential** (AN/ **ANNUBP**) : characterized by 2 or more of the following concerning findings[2]



Neurofibroma

▷ **ESSENTIAL** ◁

infiltrative, low-cellularity spindle cell neoplasm associated with a variably myxoid to collagenous stroma and a mixed cell population

▷ **DESIRABLE** ◁

- S100 positivity in the Schwann cell population, with a lattice-like CD34 pattern, highlighting the stromal component
- intraneural localization
- patient has neurofibromatosis type 1
- atypical histological features (nuclear enlargement, hypercellularity, architectural loss, mitoses) for atypical neurofibroma / atypical neurofibromatous neoplasm of uncertain biological potential in the setting of neurofibromatosis type 1, often with loss of p16 expression

Fig. 45.2 Diagnostic criteria for neurofibroma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

  - cytological atypia
  - hypercellularity
  - loss of neurofibroma architecture (on H&E and/or CD34 staining)
  - mitotic count > 0.2 mitoses/mm^2 and < 1.5 mitoses/mm^2 (equating to > 1 mitosis/50 HPF and < 3 mitoses/10 HPF of 0.51 mm in diameter and 0.2 mm^2 in area)

  AN/ANNUBP are considered premalignant or early malignant lesions that do not meet criteria for MPNST (p. 774) but have an increased risk of progression to MPNST.[3] They are not assigned a WHO grade
- **plexiform neurofibroma**
- **diffuse neurofibroma**
- **nodular neurofibroma**
- **massive soft tissue neurofibroma**: consistently benign lesions that may overlie an MPNST

Location

Usually located in the skin, typically in the dermal layer. Less commonly, may involve deeper nerves of medium-size, a nerve plexus or a major nerve trunk. They may also originate from spinal nerve roots.

Epidemiology

Most are sporadic and solitary. Multiple lesions usually occur in the context of NF1 and begin to appear around ages 5-10 years. Plexiform lesions are often congenital.[4] There is no age or gender bias.

Clinical

Cutaneous lesions are typically soft, mobile and asymptomatic. Deep tumors often produce sensory and/or motor symptoms related to the nerve of origin. The least common manifestation is a plaque-like cutaneous and subcutaneous mass of the head or neck, or as a massive enlargement of the shoulder or pelvis in a patient with NF1.

Prognosis

Isolated cutaneous neurofibromas are uniformly benign. Plexiform neurofibromas, ANNUBP and intraneural lesions originating in sizeable nerves may progress to MPNST (p. 774). Diffuse neurofibromas of the skin rarely progress.

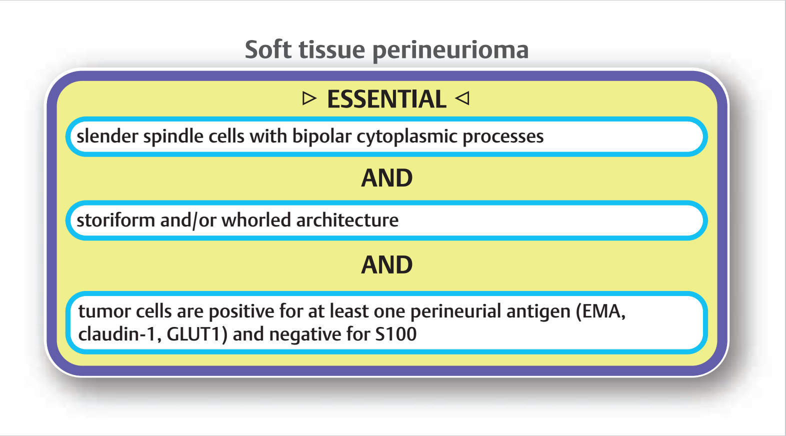
45.2.3 Perineurioma (WHO grade 1)

General information

A benign tumor comprised exclusively of neoplastic perineural cells.

Diagnostic criteria for intraneural and soft tissue perineurioma

Diagnostic criteria for soft tissue perineurioma are shown in ▶ Fig. 45.3, and for intraneural perineurioma in ▶ Fig. 45.4.[1]



Soft tissue perineurioma

▷ ESSENTIAL ◁

slender spindle cells with bipolar cytoplasmic processes

AND

storiform and/or whorled architecture

AND

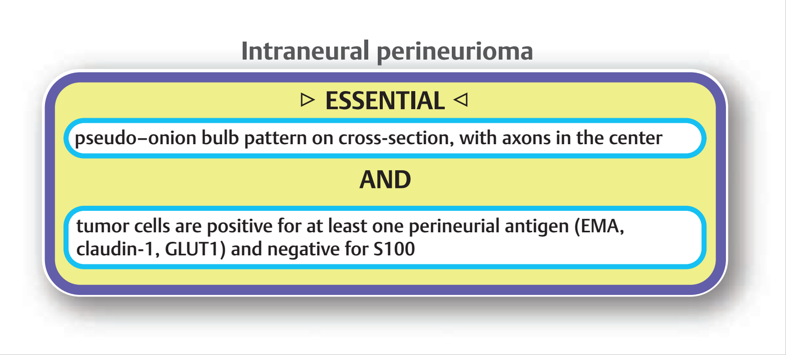
tumor cells are positive for at least one perineurial antigen (EMA, claudin-1, GLUT1) and negative for S100

Fig. 45.3 Diagnostic criteria for soft tissue perineurioma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Subtypes

See reference.[1]

- **soft tissue perineurioma**: uncommon, only ≈ 1% of soft tissue neoplasms. Arise in deep soft tissues and present as a soft tissue mass with nonspecific symptoms. Only rarely can an associated nerve be identified. Almost exclusively benign, but malignant variety does occur. Female:male ratio = 2:1. In males, hands are often affected. Discrete, but not encapsulated, diameter = 1.5–20 cm. Treatment: gross total excision is curative
- **intraneural perineurioma**: rare, only ≈ 1% of nerve sheath tumors. Usually a solitary lesion of adolescence or young adulthood, affecting primarily peripheral nerves of the extremities (cranial nerve involvement is rare). Pseudo-onion bulb formation with cylindrical enlargement of the nerve over 2–10 cm. Mitotic activity is rare, MIB-1 labeling index is low. Chromosome 22 loss is characteristic,[5] no definite association with NF1 or NF2. No gender preference. Present primarily with weakness and atrophy more often than sensory symptoms of the related nerve. Treatment: conservative sampling of lesion, not resection
- **reticular perineurioma**
- **sclerosing perineurioma**



Intraneural perineurioma

▷ ESSENTIAL ◁

pseudo–onion bulb pattern on cross-section, with axons in the center

AND

tumor cells are positive for at least one perineurial antigen (EMA, claudin-1, GLUT1) and negative for S100

Fig. 45.4 Diagnostic criteria for intraneural perineurioma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Prognosis

Intraneural perineuriomas rarely grow lengthwise and they do not extend to adjacent nerves. They do not tend to recur or metastasize.

Soft tissue perineuriomas rarely recur and metastases or malignant progression have not been reported.

Malignant perineural tumors with high mitotic activity have a poor prognosis and may metastasize.

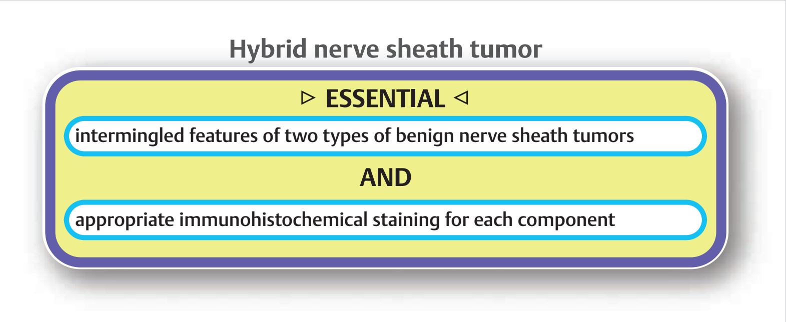
45.2.4 Hybrid nerve sheath tumors

General information

AKA benign peripheral nerve sheath tumor NOS. Rare, benign peripheral nerve sheath tumors with a mixture of more than one of: schwannoma, neurofibroma, or perineurioma.

Diagnostic criteria for hybrid nerve sheath tumor

Diagnostic criteria for hybrid nerve sheath tumor are shown in ▶ Fig. 45.5.[1]



Hybrid nerve sheath tumor

▷ ESSENTIAL ◁

intermingled features of two types of benign nerve sheath tumors

AND

appropriate immunohistochemical staining for each component

Fig. 45.5 Diagnostic criteria for hybrid nerve sheath tumor. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Subtypes

See reference.[1]

- **schwannoma/perineurioma**: the most common subtype
- **neurofibroma/schwannoma**: the second most common subtype
- **neurofibroma/perineurioma**

Prognosis

Benign neoplasms which rarely recur following excision.

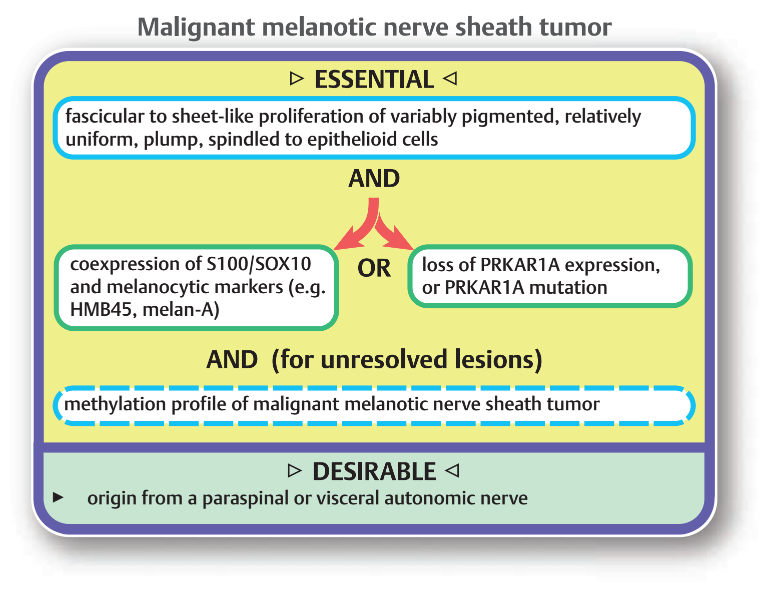
45.2.5 Malignant melanotic nerve sheath tumor (MMNST)

General information

AKA malignant melanotic Schwannian tumor. A peripheral nerve sheath tumor uniformly comprised of neoplastic cells with both Schwann cell and melanocytic features that frequently behaves aggressively. Usually arise from a spinal or autonomic nerve. There is variable association with Carney complex (p. 652). Loss of PRKAR1A protein expression with *PRKAR1A* gene mutations are found in the vast majority.

Diagnostic criteria for malignant melanotic nerve sheath tumor

Diagnostic criteria for malignant melanotic nerve sheath tumor are shown in ▶ Fig. 45.6.[1]



Malignant melanotic nerve sheath tumor
▷ ESSENTIAL ◁
fascicular to sheet-like proliferation of variably pigmented, relatively uniform, plump, spindled to epithelioid cells
AND
coexpression of S100/SOX10 and melanocytic markers (e.g. HMB45, melan-A)
OR
loss of PRKAR1A expression, or PRKAR1A mutation
AND (for unresolved lesions)
methylation profile of malignant melanotic nerve sheath tumor
▷ DESIRABLE ◁
▶ origin from a paraspinal or visceral autonomic nerve

Fig. 45.6 Diagnostic criteria for malignant melanotic nerve sheath tumor. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Epidemiology

This rare tumor of adulthood tends occur at a later age with sporadic cases (mean age: 33.2 years) than in those associated with Carney complex (mean age: 22.5 years).[6] Tumors are multiple in 20%, and these patients have a greater chance of having Carney complex than those with solitary tumors.

Prognosis

Behavior is unpredictable, and 26-44% may recur locally or metastasize even without identifiable malignant features. Recurrence rate is 47% in patients followed for more than 5 years.[1]

45.2.6 Malignant peripheral nerve sheath tumor (MPNST) (no WHO grade)

General information

A malignant spindle-cell peripheral nerve sheath tumor typically originating from a peripheral nerve, a pre-existing benign nerve sheath tumor, or in a patient with NF1. Limited Schwann cell differentiation is often seen. Characteristic molecular findings are combined genetic inactivation of *NF1*, *CDKN2A* and/or *CDKN2B*, and *SUZ12* or *EED* genes, as well as complex genomic rearrangements.

Approximately 50% are associated with NF1 (p. 638) (in NF1 they tend to occur in deep-seated plexiform neurofibromas or large intraneural neurofibromas). The lifetime risk of developing MPNST with NF1 is ≈ 9–13%.[7]

MPNSTs may spread along nerves, and 20% metastasize hematogenously, usually to lung.

Diagnostic criteria for malignant peripheral nerve sheath tumor (MPNST)

Diagnostic criteria for MPNST are shown in ▶ Fig. 45.7.[1]

Subtypes

See reference.[1]

- **epithelioid malignant peripheral nerve sheath tumor**: very rare (only ≈ 5% of MPNSTs)
- **perineurial malignant peripheral nerve sheath tumor**: very rare. Perineural features of spindle cells and whorls combined with malignant histologic features (frequent mitoses, necrosis…). These are not associated with NF1

Epidemiology

MPNST typically occur in the 20-50 year age range. In children they are usually associated with NF1 where the mean age is about 10 years less than in sporadic cases. They account for 5% of soft tissue sarcomas in patients < 20 years old.[8] Approximately 10% of MPNST are associated with a history of XRT.[9]

Prognosis

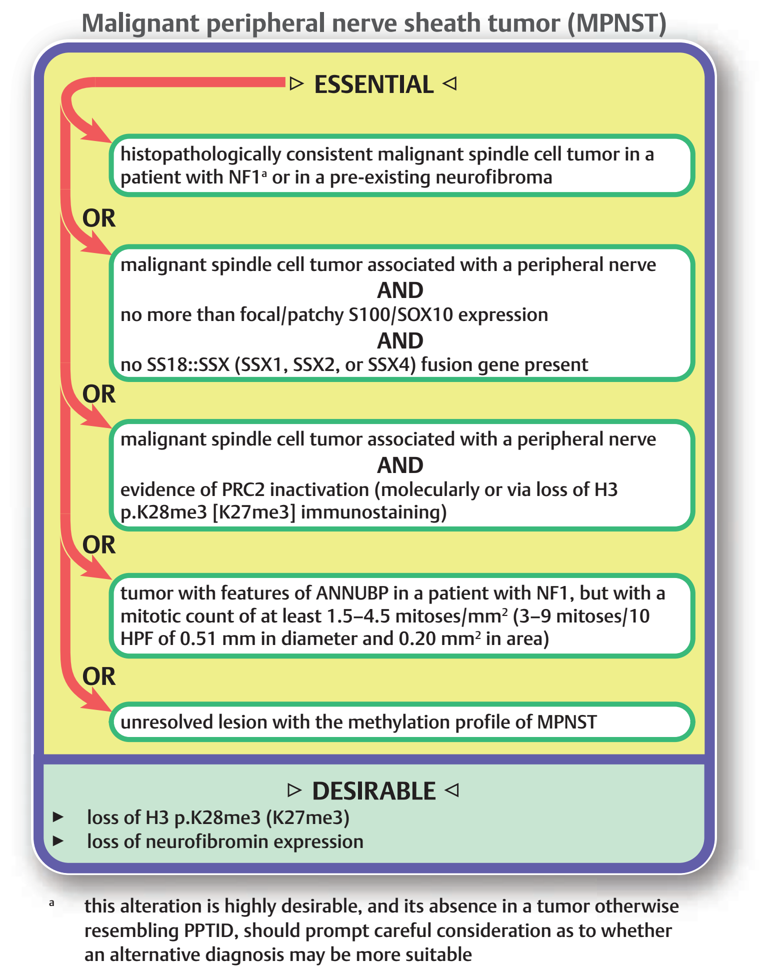
GTR, whenever possible, is the preferred treatment. The 5-year OS for sporadic MPNST is 69%, whereas in the setting of NF1 was 35%.[10] Features associated with a more favorable prognosis include[1,8]:

- smaller tumor size
- male gender and non-Hispanic White race
- no metastases at presentation
- GTR
- no association with prior XRT
- epitheliod and perineural subtypes appear to be less aggressive than conventional MPNST

45.2.7 Cauda equina neuroendocrine tumor (WHO grade 1)

General information

AKA (and formerly) paraganglioma of the cauda equina, or cauda equina paraganglioma.



Malignant peripheral nerve sheath tumor (MPNST)

▷ **ESSENTIAL** ◁

histopathologically consistent malignant spindle cell tumor in a patient with NF1[a] or in a pre-existing neurofibroma

OR

malignant spindle cell tumor associated with a peripheral nerve
AND
no more than focal/patchy S100/SOX10 expression
AND
no SS18::SSX (SSX1, SSX2, or SSX4) fusion gene present

OR

malignant spindle cell tumor associated with a peripheral nerve
AND
evidence of PRC2 inactivation (molecularly or via loss of H3 p.K28me3 [K27me3] immunostaining)

OR

tumor with features of ANNUBP in a patient with NF1, but with a mitotic count of at least 1.5–4.5 mitoses/mm^2 (3–9 mitoses/10 HPF of 0.51 mm in diameter and 0.20 mm^2 in area)

OR

unresolved lesion with the methylation profile of MPNST

▷ **DESIRABLE** ◁

- loss of H3 p.K28me3 (K27me3)
- loss of neurofibromin expression

[a] this alteration is highly desirable, and its absence in a tumor otherwise resembling PPTID, should prompt careful consideration as to whether an alternative diagnosis may be more suitable

Fig. 45.7 Diagnostic criteria for MPNST. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

A neuroendocrine tumor originating from specialized neural crest cells in the region of the cauda equina/filum terminale. CSF protein is usually increased.[11]

Diagnostic criteria for cauda equina neuroendocrine tumor

Diagnostic criteria for cauda equina neuroendocrine tumor are shown in ▶ Fig. 45.8.[1]

Cauda equina neuroendocrine tumor

▷ ESSENTIAL ◁

well-demarcated tumor with Zellballen architecture

AND

synaptophysin or chromogranin immunoreactivity in chief cells

AND

cauda equina location

AND (for unresolved lesions)

methylation profile of cauda equina neuroendocrine tumor*

▷ DESIRABLE ◁

- ► S100-positive sustentacular cells
- ► cytokeratin-positive chief cells
- ► reticulin silver stain showing typical architecture

* the DNA methylation profile and copy-number profiles of cauda equina neuroendocrine tumors are distinct from those of paragangliomas from other locations

Fig. 45.8 Diagnostic criteria for cauda equina neuroendocrine tumor. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Location

Most spinal paragangliomas occur in the region of the cauda equina, and most of these are intradural and are attached to the filum terminale.

Clinical

Typically present with low back bain and radiculopathy. Numbness, paraparesis and sphincter disturbance are less common. Even less common are cauda equina syndrome or symptoms of increased ICP (including papilledema). Acute paraparesis, spinal subarachnoid hemorrhage,[11] or neuroendocrine symptoms due to catecholamine secretion (paroxysmal or sustained hypertension, palpitations, diaphoresis and H/A) are extremely rare.

Imaging

On imaging, these tumors are usually indistinguishable from other common neoplasms of the area (schwannomas, myxopappilary ependymomas). The diagnosis may be suggested preoperatively in the infrequent case demonstrating serpiginous dilated and ectatic blood vessels, sometimes with a “cap sign” (low-intensity rim on T2WI or GRASS or SWI MRI due to hemosiderin from prior hemorrhages).[11]

Histology

The tumors are well differentiated. Uniform round or polygonal chief (type I) cells congregate in lobules (Zellballen) encompassed by a barely discernible single layer of susentacular (type II) cells.

Mature ganglion cells and a Schwann cell component (gangliocytic neuroendocrine tumors) are found in ≈ 25%. Scattered mitotic figures, areas of focal hemorrhagic necrosis and nuclear pleomorphism may be seen but are not prognostically significant.

Prognosis

The preponderance of these tumors are slow growing. The recurrence rate following GTR is very low.[12] Dissemination of tumor through the CSF may occur.

45.3 Vestibular schwannoma

45.3.1 General information

Key concepts

- histologically benign tumor of cranial nerve VIII located in the cerebellopontine angle (CPA)
- usually arises from inferior division (controversial) of the vestibular portion of the VIII nerve
- about 1 in 500 persons will develop this tumor during their lifetime
- 3 most common early symptoms (clinical triad): hearing loss (insidious and progressive), tinnitus (high pitched) and dysequilibrium (true vertigo is uncommon)
- W/U: All patients: ✓ MRI with IAC protocol (p. 241), ✓ audiometrics (pure tone audiogram and speech discrimination). In addition for small VSs (≤ 1.5 cm dia): ✓ ENG, ✓ cVEMP, ✓ ABR
- histology: comprised of Antoni A (narrow elongated bipolar cells) and Antoni B fibers (loose reticulated). Compared to most schwannomas, Antoni A fibers predominate
- choice of management option (observation, surgery, XRT or chemotherapy [Avastin®]) depends heavily on tumor size, growth, hearing status, VII function and presence of NF2 (see text)

Owing to the commonality and intricacies, this particular schwannoma receives a section devoted just to this tumor.

Vestibular schwannoma (VS) is a histologically benign Schwann-cell sheath tumor that usually arises from the inferior division of the *vestibular nerve* (not the cochlear portion). VSs arise as a result of the loss of a tumor-suppressor gene on the long arm of chromosome 22 (in sporadic cases this is a somatic mutation; in neurofibromatosis Type 2 (NF2) this is either inherited or represents a new mutation that may then be transmitted to offspring).

Obsolete terms, included for reference, should be avoided[13,14]: acoustic neuroma, acoustic neurinomas (neurinoma is an obsolete term for schwannoma), neurolemoma or neurilemmoma.

45.3.2 Epidemiology

The most common non-malignant nerve sheath tumor, comprising 8–10% of tumors intracranial tumors.[15] Annual incidence quoted by CBTRUS is 1.51 cases per 100,000 population in the U.S.[16]—over the past couple decades the incidence has increased and the typical size at diagnosis has decreased, partially as a result of the proliferation of MRI scans.[17] Other estimates disclose a higher incidence of 3.0-5.2/100,000.[18,19] The highest incidence occurs in patients aged ≥ 70 years, peaking at 20.6 per 100,000 person-years.[19] There is no gender differential.[19] At least 95% are unilateral.

► **Neurofibromatosis Type 2.** The incidence of vestibular schwannomas (VS) is increased in in neurofibromatosis Type 2 (NFT2) (p. 640) (central NFT), with bilateral VS being a hallmark. Any patient < 40 yrs old with unilateral VS should be evaluated for NFT2. Cytologically, the VSs of NFT2 are identical to sporadic cases; however, in NFT2 the tumors form grape-like clusters that may infiltrate the nerve fibers (unlike most sporadic VSs which *displace* the eighth nerve).

45.3.3 Pathology

Tumors are composed of Antoni A fibers (narrow elongated bipolar cells) and Antoni B fibers (loose reticulated). Verocay bodies are also seen, and consist of acellular eosinophilic areas surrounded by parallel arrangement of spindle shaped schwann cells (they are not a cell type). Tumor-associated macrophages (TAMs) may be associated with increased risk of recurrence following STR.

45.3.4 Clinical

Symptoms

General information

VSs typically become symptomatic after age 30. Symptoms are shown in ▶ Table 45.1. The type of symptoms are closely correlated with tumor size. Most initially cause the triad of ipsilateral sensorineural hearing loss, tinnitus and balance difficulties. Larger tumors can cause facial numbness, weakness or twitching, and possibly brainstem symptoms. Rarely, a large tumor may produce hydrocephalus. With current imaging modalities (CT and especially MRI), increasing numbers of smaller lesions are being detected.

Table 45.1 Symptoms in vestibular schwannoma[15,20,21,22]

Symptom	%
hearing loss	95
tinnitus	55
dizziness/imbalance	61
H/A	32
facial numbness	18
facial weakness	17
diplopia	10
N/V	9
otalgia	9
change of taste	6
vertigo	8
continuous dizziness	3

Acoustic nerve (Cr N VIII) symptoms

Unilateral sensorineural hearing loss, tinnitus and dysequilibrium are the most frequent symptoms. For years it was taken for granted that hearing loss was due to compression and/or stretching of the VIII nerve by the tumor; however, recent evidence suggests possible toxic factors secreted by the tumor cause cochlear damage.[23,24]

Hearing loss is insidious and progressive in most (c.f. the hearing loss in Meniere disease which fluctuates); however, 10% report sudden hearing loss (see below). 70% have a high frequency loss pattern, and word discrimination is usually affected (especially noticeable in telephone conversation).

The tinnitus is usually high-pitched.

Unsteadiness manifests primarily as difficulty with balance; true vertigo occurs in < 20%.

Sudden hearing loss: The differential diagnosis for sudden hearing loss (SHL) is extensive.[25] *Idiopathic* SHL (i.e., no identified etiology: must rule out neoplasm, infection, autoimmune, vascular, and toxic causes) represents 90% of cases[26] and occurs in an estimated 5-20 per 100,000 population.[27] 1% of patients with SHL will be found to have a VS, and SHL may be the presenting symptom in 1–14% of patients with VS.[28] SHL with VS is presumably due to an infarction of the acoustic nerve, or acute occlusion of the cochlear artery. Treatment options for SHL include:

1. steroids: e.g., prednisone 60 mg PO q d × 10 d then tapered.[28] Ideally initiated within 2 weeks of onset of SHL[26]
2. there is no high-quality data supporting addition of antiviral therapy (e.g., famciclovir)[29,30]
3. ✖ not recommended
   - heparin has been shown *not* to be of help
   - there is also no high quality data to support: rest, restriction of salt, alcohol or tobacco, or use of thrombolytics

Trigeminal (Cr N V) and facial (Cr N VII) nerve symptoms

Otalgia, facial numbness and weakness, and taste changes occur as the tumor enlarges and compresses the fifth and seventh nerves. These symptoms usually do not occur until the tumor is > 2 cm. This highlights an interesting paradox: facial weakness is a rare or late occurrence, even though the 7th nerve is almost always distorted early; whereas facial numbness occurs sooner once trigeminal compression occurs (often in the presence of normal facial movement), despite the fact that the 5th nerve is farther away.[31] This may be due to the resiliency of motor nerves relative to sensory nerves.

Brainstem and other cranial nerve symptoms

Larger tumors cause brainstem compression (with ataxia, H/A, N/V, diplopia, cerebellar signs, and if unchecked, coma, respiratory depression and death) and lower cranial nerve (IX, X, XII) palsies (hoarseness, dysphagia…). Obstruction of CSF circulation by larger tumors (usually > 4 cm) may produce hydrocephalus with increased ICP.

Rarely, 6th nerve involvement may cause diplopia.

Signs

Hearing loss due to VIII involvement is the earliest cranial nerve finding. 66% of patients have no abnormal physical finding except for hearing loss (for other findings, see ▶ Table 45.2).

Since hearing loss is sensorineural, **Weber test** (p. 611) will lateralize to the uninvolved side, and if there is enough preserved hearing, **Rinne test** (p. 611) will be positive (i.e., normal; air conduction > bone conduction) on both sides.

Facial nerve (VII) dysfunction due to VS is uncommon before treatment. Facial nerve function is commonly graded on the House and Brackmann scale (▶ Table 45.3).

Vestibular involvement causes nystagmus (may be central or peripheral) and abnormal electronystagmography (ENG) with caloric stimulation.

Table 45.2 Signs in 131 vestibular schwannomas (excluding hearing loss)[15]

Sign	%
abnormal corneal reflex	33
nystagmus	26
facial hypoesthesia	26
facial weakness (palsy)	12
abnormal eye movement	11
papilledema	10
Babinski sign	5

Table 45.3 Clinical grading of facial nerve function (House and Brackmann[32])

Grade	Function	Description
1	normal	normal facial function in all areas
2	mild dysfunction	1. gross: slight weakness noticeable on close inspection; may have very slight synkinesis 2. at rest: normal symmetry and tone 3. motion: a) forehead: slight to moderate movement b) eye: complete closure with effort c) mouth: slight asymmetry
3	moderate dysfunction	1. gross: obvious but not disfiguring asymmetry: noticeable but not severe synkinesis 2. motion: a) forehead: slight to moderate movement b) eye: complete closure with effort c) mouth: slightly weak with maximal effort
4	moderate to severe dysfunction	1. gross: obvious weakness and/or disfiguring asymmetry 2. motion: a) forehead: none b) eye: incomplete closure c) mouth: asymmetry with maximum effort
5	severe dysfunction	1. gross: only barely perceptible motion 2. at rest: asymmetry 3. motion: a) forehead: none b) eye: incomplete closure
6	total paralysis	no movement

45.3.5 Evaluation

Diagnostic studies – overview

1. brain MRI without and with contrast: include navigation and IAC protocol (p. 241) (if available). If MRI is contraindicated, then a CT scan without and with contrast. Tumor size is graded using the Koos system (▶ Table 45.7)[33]
2. temporal bone CT for detailed bony anatomy if surgery is contemplated
3. audiometric evaluation (see text below for explanation & indications):
   a) pure tone audiogram (see below)
   b) speech discrimination evaluation (see below)
   c) patients with small VSs (≤ 1.5 cm dia) also get:
      - ENG: (p. 782) assesses *superior* vestibular nerve
      - VEMP: (p. 782) assesses *inferior* vestibular nerve
      - ABR: (p. 782) prognosticates chance of hearing preservation

Audiometric and audiologic studies

General information

Baseline studies are helpful for management treatment decisions and for later comparison and to assess the contralateral ear.

Practice guideline: Otologic & audiologic screening for vestibular schwannomas

- Level III[22]: patients with ≥ 10 dB interaural hearing difference at ≥ 2 frequencies or ≥ 15 dB at 1 frequency should have an MRI to look for VS. Selectively doing MRI for ≥ 15 dB interaural difference at 3000 Hz alone may minimize negative MRIs
- Level III[22]: MRI is recommended for asymmetric tinnitus, although the yield is low (< 1% positive for VS)
- Level III[22]: MRI is recommended for sudden sensorineural hearing loss; however, the yield is low (< 3% positive for VS)

Abbreviations: MRI = brain MRI (see imaging guidelines (p. 782)); dB = decibels.

Pure tone audiogram (PTA)

May be useful as first-step screening test. Air conduction assesses the entire system, bone conduction assesses from the cochlea and proximally. PTA assesses the functionality of hearing (to help in treatment decision making) and acts as a baseline for future comparison. The pure tone average (also abbreviated PTA) is a single numerical score that is an *average* of the thresholds for frequencies across the audio spectrum (at 500, 1000 & 2000 Hz). On a standard audiogram, X's denote the left ear (AS) and O's denote the right ear (AD).

Progressive unilateral or *asymmetric* sensorineural hearing loss of high tones occurs in > 95% of VSs.[34] High-frequency hearing loss also happens to be the most common type of hearing loss with age or with noise-induced sensorineural hearing loss, but is usually symmetrical. Only ≈ 1 in 1000 patients with asymmetric hearing have a VS.[13] Other causes of asymmetrical sensorineural hearing loss[35]: other CPA lesions (e.g., meningioma), inner ear lesions, intraaxial lesions (including brainstem infarctions), multiple sclerosis. On hearing screening tests, an unexplained PTA difference from one ear to the other > 10–15 dB is suspicious and should be investigated further.

Speech discrimination evaluation

Speech discrimination is maintained in conductive hearing loss, moderately impaired in cochlear hearing loss, and worst with retrocochlear lesions. No longer used for diagnostic purposes; a score of 4% suggests a retrocochlear lesion, as does a score that is worse than would be predicted based on PTA testing (the speech recognition threshold should be similar to PTA thresholds below 4 kHz). Useful in determining serviceability of hearing and prognosticating for hearing preservation surgery.

Table 45.4 Open-set word recognition score

Class	WRS (%)
I	70–100
II	50–69
III	1–49
IV	0

Open-set word recognition score (WRS ▶ Table 45.4) is a more sensitive measure of communication ability than PTA.

Definition of serviceable hearing

There are many definitions of what constitutes serviceable hearing. Also, even nonserviceable hearing can offer some benefit. If WRS is good (≥ 70%) but PTA is poor, a hearing aid may provide significant benefit.

Two commonly used scoring systems for hearing are shown here:

1. Modified **Gardener-Robertson** system for grading hearing: shown in ▶ Table 45.5. Class I patients may use a phone on that side, class II patients can localize sounds.
2. The American Academy of Otolaryngology – Head and Neck Surgery Foundation (AAO-HNS) hearing classification system[36]: shown in ▶ Table 45.6.

Some definitions of serviceable hearing (see text that follows for details):

1. AAO-HNS class A or B
2. Gardner-Robertson system
   - "50/50 rule": Gardner-Robertson class I or II (pure tone audiogram threshold ≤ 50 dB and speech discrimination score ≥ 50%)
   - some prefer a "70/30 rule" (70% WRS, 30 dB PTA)
3. in a patient with good hearing in the contralateral ear, a speech discrimination score (SDS) of < 70% in the affected ear is not considered good hearing; whereas if the contralateral ear is totally deaf, an SDS of ≥ 50% can be useful[39]

Table 45.5 Gardener and Robertson modified hearing classification[a]

Class	Pure tone audiogram[b](dB)	Speech discrimination[b]	Description	Clinical utility
I	**0–30**	**70–100%**	**good-excellent**	**serviceable**
II	**31–50**	**50–69%**	**serviceable**	
III	51–90	5–49%	non-serviceable	non-serviceable
IV	91-max	1–4%	poor	
V	not testable	0	none	

[a]modification[37] of the Silverstein and Norrell system[38]
[b]if PTA and speech discrimination score do not qualify in the same class, use the lower class
Boldface grades are generally considered serviceable hearing.

Table 45.6 American Academy of Otolaryngology–Head and Neck Surgery Foundation hearing classification system

Class	Pure tone threshold (dB)[a]		Speech discrimination score[b] (%)	Clinical utility
A	**≤ 30**	AND	**≥ 70**	**"useful"**
B	**> 30 AND ≤ 50**	AND	**≥ 50**	
C	> 50	AND	≥ 50	"aidable"
D	any level		< 50	"nonfunctional"

[a]average of pure tone hearing thresholds by air conduction at 0.5, 1, 2 & 3 kHz
[b]speech discrimination at 40 dB or maximum comfortable loudness
Boldface classes are generally considered serviceable hearing.

Additional audiometric tests that are helpful with small VSs (≤ 1.5 cm diameter)

The **ENG (caloric testing) and cVEMP** evaluate the superior and inferior division of the vestibular nerve (VN) respectively. The inferior VN is closer to the cochlear nerve than the superior VN (▶ Fig. 1.9), and small tumors (≤ 4 mm) of the inferior VN tend to be deeper and closer to the cochlear nerve than similarly sized tumors of the superior division which tend to be more superficial and more easily removed.

Electronystagmography (ENG): Only tests the horizontal semicircular canal ∴ assesses the *superior* vestibular nerve which innervates it. Normally, each ear contributes an equal portion of the response. The ENG is considered abnormal if there is > 20% difference between the two sides. Response may be normal with a small tumor arising from the *inferior* division of vestibular nerve. NB: the vestibular nerve may continue to function until almost all of the nerve fibers are affected. Mnemonic for the directionality of the nystagmus (direction is classified based on the fast phase of the nystagmus). COWS (Cold Opposite, Warm Same). NB: this differs from caloric testing for brain death (p. 323) and is a source of confusion.

Vestibular evoked myogenic potential (VEMP): Most commonly cVEMP ("c" for cervical to denote that the muscle recorded in the sternocleidomastoid, oVEMP (ocular) and tVEMP (triceps) are used much less frequently).

cVEMP assesses the *inferior* vestibular nerve by imparting acoustic energy to the saccule.[40] Independent of hearing (can be done even with deafness from profound sensorineural hearing loss). Electrodes are placed on sternocleidomastoid muscle (SCM).

Auditory brainstem responses (ABR): AKA BAER (p. 252). The most common findings are prolonged I-III and I-V interpeak latencies. No longer used for diagnostic purposes (sensitivity is only ≈ 88–90% (i.e., will miss 10–12% of VSs) and specificity is only 85%). ABR is useful for prognostication—poor wave morphology correlates with lower chance of preserving hearing (even with good hearing).

Radiographic evaluation

Imaging guidelines

Practice guideline: Imaging for vestibular schwannomas

For the full guideline, see reference.[41]

Initial pre-op evaluation to detect VS
- Level III[41]: high-resolution T2 and contrast-enhanced T1 MRI should be used
- Level III[41]: standard T1, T2 FLAIR & DWI MRI sequences in axial, coronal, and sagittal plane may be used

Pre-op surveillance for a known VS if an observation ("watch-and-wait") approach is being used
- Level III[41]: pre-op surveillance for VS growth should be either contrast-enhanced 3-D T1 magnetization prepared rapid acquisition gradient echo (MPRAGE) or high-resolution T2 MRI (including FIESTA or CISS sequences[a])
- Level III[41]: MRIs should be obtained annually for 5 years, with lengthening of the interval after that if stable
- Level III[41]: because of more variable growth rates, NF2 patients with VS should be imaged more frequently at first and then annually once the growth rate is determined
- Level III[41]: in NF2 patients, consider non-contrast MRIs if high-resolution T2 (including CISS or FIESTA) MRI adequately visualizes the tumor

Pre-op evaluation in preparation for surgery
- Level III[41]: T2 MRI may be used to augment visualization of the course of the facial nerve
- Level III[41]: counsel adults with cystic VS that their tumors may more often exhibit rapid growth, lower rates of complete resection, and inferior outcome of facial nerve function immediately post-op but similar to noncystic VS over time
- Level III[41]: the degree of lateral IAC involvement adversely affects facial nerve and hearing outcomes

Postop evaluation
- Level II[41]: post-contrast 3-D T1 MPRAGE should be used for nodular enhancement suspicious for recurrence

- Level III[41]: post-op imaging
  - following GTR: an MRI may be considered as late as 1 yr post-op to confirm GTR
  - for < GTR: more frequent MRIs are suggested—annually for 5 years, with adjustments for changes in nodular enhancement. NB: tumor volume decreases by ≈ 35% in the 1st 3 months after STR, and 32% do not enhance in the immediate post-op period[42]
- Level III[41]: after resection of one VS in an NF2 patients with bilateral VS, the growth of the contralateral VS may accelerate and more frequent imaging should be considered until the growth pattern is established

Abbreviatons: GTR = gross total resection; STR = subtotal resection; IAC = internal auditory canal.
[a] FIESTA (p. 241) or CISS (p. 241) may improve visualization of the tumor and nerves in CSF

Differential diagnosis

See Cerebellopontine angle (CPA) lesions (p. 1647). The major differentials on imaging are:

1. CPA meningioma; see differentiating features (p. 1648)
2. schwannoma of adjacent cranial nerve, including mainly:
   a) facial nerve (Cr. N. VII) schwannoma: can arise anywhere along the course of Cr. N. VII
      1. imaging: may be dumbbell shaped due to extension from the ICA fundus through the labyrinthine segment and into the geniculate fossa. When isolated to the CPA, they may be indistinguishable from VS[43]
      2. clinical: typically present with facial weakness (slowly progressive or sudden), often preceded by facial twitching, facial nerve pain, hemifacial spasm and decreased lacrimation.[44] In patients thought to have Bell's palsy, a facial nerve neuroma was found to be the cause in 5%, and 27% had normal facial nerve function[45]
   b) trigeminal (Cr. N. V) schwannoma

CT scan

CT with IV contrast is second choice for imaging modality. If MRI is contraindicated and clinical suspicion of VS is strong but the CT is negative, small lesions may be visualized by introducing 3–4 ml of subarachnoid air via lumbar puncture, and scanning the patient with the affected side up (to trap air in region of IAC), non-filling of the IAC is indicative of an intracanalicular mass. Even with air contrast, CT was normal in 6% in Mayo series.[15]

Many VSs enlarge the ostium of the IAC (called trumpeting). Normal diameter of the IAC: 5–8 mm. 3–5% of VSs do not enlarge the IAC on CT (percentage is likely higher in small VSs vs. large ones).

Thin-cut temporal bone CT should be obtained for operative planning. Important features to identify:

- for middle fossa approach: bony coverage of geniculate ganglion to identify dehiscence
- for translab approach:
  - extent of pneumatization of the mastoid and position of sigmoid sinus. An anterior sinus with poorly pneumatized mastoids can indicate a tight space for this approach
  - position of the jugular bulb. If high riding, can indicate a tight space in translab approach
- for retrosigmoid transmeatal approach: location and thickness of bone coverage over the posterior semicircular canal and vestibular aqueduct. The extent of peritubular air cells and retro facial air cells needs to be assessed in planning the approach and preventing CSF leaks

MRI

MRI (▶ Fig. 45.9) is the diagnostic procedure of choice (see Practice guideline (p. 782) for sequence recommendations) with sensitivity close to 98% and almost 0% false positive rate. Characteristic findings: round or oval enhancing tumor centered on IAC. Large VSs (> 3 cm dia) may show cystic appearing areas on CT or MRI; in actuality these areas are usually solid. Adjacent trapped CSF cisterns may also give cystic appearance. In a pilot study, hyperintensity on T2 has been associated with soft and suckable tumors at the time of surgery[46] and a trend towards better VII function preservation.

Tumor size is graded using the Koos system (▶ Table 45.7).[33]

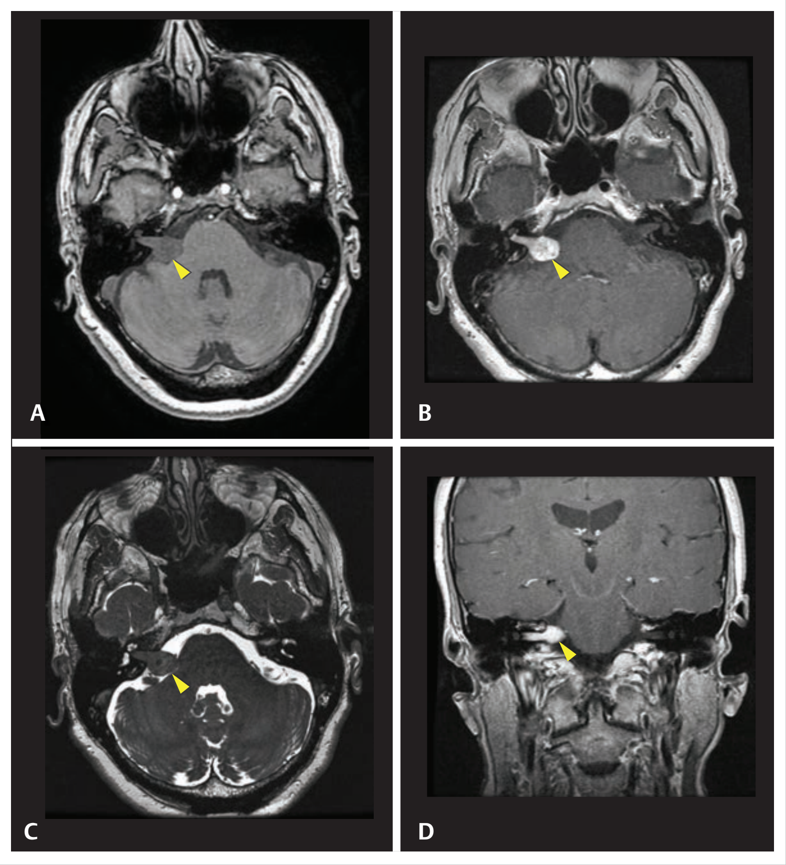


Fig. 45.9 Vestibular schwannoma, right-sided.
This Koos grade III tumor is identified by *yellow arrowheads*.
Image: MRI, A: axial T1 sequence, B: axial T1 + contrast, C: axial FIESTA scan, D: coronal T1 + contrast.

Table 45.7 Koos grading system for vestibular schwannomas & approximate corresponding volume[a]

Grade	Tumor extent[33]	Average tumor volume[b] [47] (cc)
I	intracanalicular tumor	0.3
II	protrusion into CPA, but not reaching the brainstem	0.6
III	extends to brainstem surface without displacing it	1.8
IV	displaces brainstem and cranial nerves	4.2[c]

[a] volume measurements are not part of the Koos grading system and are included for interest as it may impact stereotactic radiosurgery decisions
[b] volume measurements are from 235 patients undergoing gamma knife treatment and this may be a source of selection bias for volume measurement
[c] grade IV was a very heterogeneous group, and Minderman & Schlegel proposed adding a category V for tumors > 6 cc

45.3.6 Management

Management options

Management options include:

1. expectant management ("wait and scan" approach): follow symptoms, hearing (audiometrics) and tumor growth on serial imaging (MRI or CT) (see guidelines (p. 782) for imaging recommendations). Intervention is performed for progression. Growth patterns observed:
   a) little or no growth: applies to most (83%) VSs confined within the IAC (▶ Table 45.7, Koos grade I) and to 30% extending into CPA (▶ Table 45.7, Koos grade II) (see natural history of growth below)
   b) slow growth ≈ 2 mm/yr
   c) rapid growth: ≥ 10 mm/yr
   d) a few actually shrink[17]
2. radiation therapy (alone, or in conjunction with surgery)
   a) external beam radiation therapy (EBRT)
   b) stereotactic radiation
      - stereotactic radiosurgery (SRS) (p. 1903): single dose. As there is little difference in radiographic control at different doses, single dose SRS < 13 Gy is recommended for hearing preservation and to minimize new onset or worsening of cranial nerve deficits (Level III[48])
      - stereotactic radiotherapy (SRT) (p. 1903): fractionated
3. surgery: approaches include the following (see below for details)
   a) retrosigmoid (AKA suboccipital): may be able to spare hearing
   b) translabyrinthine (and its several variations): sacrifices hearing, may be slightly better for sparing VII
   c) middle fossa approach (extradural subtemporal): only for small lateral VSs
4. chemotherapy: some preliminary promise for progressive NF2-related vestibular schwannomas with bevacizumab (Avastin®), an anti-VEGF (vascular endothelial growth factor) monoclonal antibody (see below). Side effects: hemorrhage occurs in ≈ 7% due to vessel necrosis

Patient/tumor factors influencing management decisions

In addition to the usual factors involved in the decision process with brain tumors (e.g., the patient's general medical condition, age, natural history, etc.) elements unique to VSs include: chances of preserving VII & V nerve function and hearing (in those with serviceable hearing) (all of which are related to tumor size), and the presence of NF2.

Specifics:

1. natural history of growth
   a) usual quoted range: ≈ 1–10 mm/yr. However this can be quite variable
   b) strictly intracanalicular tumors: only 17% grew outside the meatus (in 552 VSs over 3.6 years mean follow-up (230 were intrameatal at time of diagnosis, 322 had extrameatal extension)[17])
   c) extrameatal tumors (with extension into CP angle): 30% grew > 2 mm (in 522 VSs over 3.6 years mean follow-up[17])
   d) VSs that did not grow in the 5 years after diagnosis did not grow after that
   e) 6% actually decrease in size[49]
2. natural history of hearing function in untreated intracanalicular VSs in AAO-HNS Group A (▶ Table 45.6) patients. Rule of thumb for patients presenting with serviceable hearing (SH): 75% retain SH at 3 years, 60% at 5 years, and 40% at 10 years.[50] Details[51]:
   a) 50% deteriorated to a lower class over 4.6 years (loss of ≥ 10 dB PTA or ≥ 10% SDS)
   b) after 4.6 years of observation, the proportion of patients eligible for hearing preservation treatment (as determined by a word recognition score class I [70–100% SDS]) was reduced to 28% (a 44% reduction) and by AAO-HNS class A to 9% (a 53% reduction)
   c) the risk of losing hearing was not related to: age, gender, VS size (all tumors were intracanalicular) or tumor sublocalization (fundus, central, porus)
   d) hearing loss was positively correlated to the absolute volumetric tumor growth rate (tumors that eventually expand out of the IAC have a faster rate and degree of hearing loss compared to tumors remaining in the IAC)
   e) the risk of losing hearing was significantly lower for patients with 100% word recognition score. Over 4.6 years observation, 89% remained in WRS class I (▶ Table 45.4) compared to only 43% for patients with only a small (1–10%) loss of WRS at diagnosis
3. size: as tumors exceed 15 mm diameter, treatment complications increase
   a) significantly lower chance for hearing preservation
   b) increased incidence of VII injury

4. presence of cysts: cystic tumors may display sudden and dramatic growth[17]
5. serviceable hearing: see Definition of serviceable hearing (p. 781)
6. hearing in contralateral ear

Surgical factors – hearing preservation following microsurgery (MS) in sporadic VS

The probability of maintaining serviceable hearing following GTR of an *intracanalicular* VS for retrosigmoid vs. middle fossa approach in experienced hands is shown in ▶ Table 45.8 and is so similar that the choice of approach with regard to hearing preservation should be made on the basis of the expertise of the surgical team.[52]

If class A hearing (≤ 30 dB PTA, ≥ 70% WRS) is initially preserved following gross total resection of a VS, the probability of maintaining serviceable hearing (≤ 50 dB PTA, ≥ 50% WRS) is 80–100% at 2 years, 80–100% at 5 years, and 70–90% at 10 years.[52]

Table 45.8 Probability of maintaining SH[a] after GTR microsurgery[b] [52]

Time post op	Probability of preserved SH[a]	
	Retrosigmoid approach	Middle fossa approach
immediate post-op	40-60%	50-70%
2 years	40-60%	40-60%
5 years	30-50%	40-60%
10 years	20-40%	20-40%

[a] SH (serviceable hearing): ≤ 50 dB PTA, ≥ 50% WRS
[b] following gross total resection (GTR) of a sporadic intracanalicular VS in experienced hands

Practice guidelines for management of sporadic VS

Practice guideline: Hearing preservation outcomes with vestibular schwannomas

For the full guideline, see reference.[53]

Observation vs. intervention recommendation

- Level III[48]: for VS without tinnitus that are intracanalicular (▶ Table 45.7, Koos grade I) or < 2 cm, observation[a] is recommended since it does not have a negative impact on tumor growth or hearing preservation

Hearing preservation with observation[a] in sporadic VS

- Level III[53]: for VS < 2 cm with serviceable hearing, chances of hearing preservation are > 75–100% @ 2 years, > 50–75% @ 5 years, and > 25–50% @ 10 years
- Level III[53]: for VS < 2 cm with AAO-HNS class A or GR grade I (▶ Table 45.5) hearing, chances of hearing preservation are > 75%-100% @ 2 years, and > 50%-75% @ 5 years. Data was insufficient for chances @ 10 years

Hearing preservation following SRS[b] in sporadic VS

- Level III[53]: for serviceable hearing pre-SRS, chances of hearing preservation are > 50–75% @ 2 & 5 years, and > 25–50% @ 10 years
- Level III[53]: for AAO-HNS class A or GR grade I (▶ Table 45.5) hearing pre-SRS, chances of hearing preservation are > 75%-100% @ 2 years, > 50%-75% @ 5 years, and > 25–50% @ 10 years

Hearing preservation following middle fossa or retrosigmoid MS in sporadic VS

- Level III[53]: for sporadic VS < 2 cm with serviceable hearing pre-op, chances of hearing preservation are > 25%-50% immediately post-op, and @ 2, 5 & 10 years post-op
- Level III[53]: for sporadic VS < 2 cm with AAO-HNS class A or GR grade I (▶ Table 45.5) hearing pre-SRS, chances of hearing preservation are > 50%-75% immediately post-op and @ 2 & 5 years post op, and > 25%-50% @ 10 years

[a] observation consists of serial MRI evaluations as discussed in (p. 782)

[b] single dose SRS using modern dose planning (generally ≤ 13 Gy to the tumor margin, or ≤ 12 Gy to the tumor margin and cochlear dose ≤ 4 Gy)

Abbreviations: MS = microsurgery; SRS = stereotactic radiosurgery.

▶ **Modified Delphi Study Consensus for sporadic VS.** The Modified Delphi Study for sporadic VS published in 2020[52] issued 103 consensus statements related to this topic, and the reader is highly encouraged to review the results. Some FAQs derived from these statements are presented in ▶ Table 45.9, along with the strength of the opinion.

Table 45.9 Some FAQs based on the modified Delphi Study on VS[52]

FAQ & Answer	Statement numbers
Q: Is poorer baseline hearing associated with a greater probability of progression to non-serviceable hearing regardless of treatment[a]? A: Yes (strong consensus)	#10, 25, 44
Q: Does larger tumor size increase the probability of progression to non-serviceable hearing[a]? A: Yes (strong consensus)	#7, 24, 40
Q: What is the optimal form of radiation for treating VS? A: There is no clear clinical advantage of fractionated radiation vs. SF-SRS, or for LINAC vs. Gamma radiation. Proton beam and intensity modulated radiation are not established modalities for treating VS (strong consensus)	#4, 74
Q: Is GTR associated with a greater probability of losing SH compared to near-total & subtotal resection? A: Yes (strong consensus)	#31
Q: When should patients undergoing observation be treated? A: Treatment (MS, SF-SRS or fractionated-SRS) should be offered at the first sign of unequivocal tumor growth (strong consensus)	#72

[a] regardless of treatment: SF-SRS, MS or observation

Abbreviations: GTR = gross total resection; MS= microsurgery; SF-SRS = single fraction stereotactic radiosurgery; SH (serviceable hearing): ≤ 50 dB PTA, ≥ 50% WRS

Management algorithm

Note: there are no Level I recommendations for most aspects of VS management. Some recommendations here differ from the published guidelines quoted above. The reader is encouraged to review the available information and determine their preferred approach which may differ from either of these strategies.

- small tumors (< 15 mm diameter) with perfect hearing (WRS 100%):
  observe radiographically (CT or MRI scan) plus serial hearing tests (so-called “wait and scan”):
  - scan: recommend treatment for growth > 2 mm between studies. Scan schedule guide:
    - every 6 months × 2 years after diagnosis, then (if stable)
    - annually until 5 years after diagnosis, then (if stable)
    - at years 7, 9, and 14 after diagnosis[17]
  - annual audiology evaluations
    - hearing deterioration (WRS < 100%) but no growth: see below
    - rationale: in patients with small tumors and normal WRS, comparing the results of hearing preservation following surgery or SRS to the natural history, the conclusion is that *established tumor growth* should be the main determinant for treatment[39]
- small tumors with serviceable hearing: management is very controversial
  - in general, patients with serviceable hearing but WRS < 100% have a 50% chance of preserving their serviceable hearing (50/50 rule or AAO-HNS class A or B) with either observation, SRS or microsurgical resection. Observation is sstrongly recommended as the initial management[52]
  - hearing preservation rates better than 50% have been reported for both microsurgery and radiosurgery in very selected patients (smaller tumors, located medially in the IAC, intact pre-op ABR amplitudes and latencies)
  - decisions to try to beat the natural history (50% chance of hearing loss at 10 years) should be very individualized based on tumor factors (size, location) and patient factors (ABR, age, co-morbidities, preferences)

  - final management decisions are often dictated by non medical reasons (patient's perception, social situation, financial considerations, support system, etc.)
- medium size tumors (15–25 mm diameter)
  - tumors > 15–20 mm should be treated.[17,39] This is mostly true for young patients
  - close observation to establish growth is a valid option in older patients or patients with medical co-morbidities
  - complication rate increases and facial outcome worsens with increasing tumor size
  - NF2 patients present a challenge and should be evaluated individually. In general the success rate in the management of their tumors is lower (higher cranial nerve deficit and higher recurrence rate).[54,55] Early management is considered more favorable for good outcome.[56] A retrospective study found significant hearing improvement and tumor shrinkage in > 50% of NF2 patients with progressive VS using bevacizumab (Avastin®) (see above)

- large tumors (> 25 mm diameter): treatment is recommended
  - microsurgical resection is favored to reduce mass effect and decompress the brainstem
  - SRS is also useful in larger tumors for older patients or those with significant co-morbidities
  - for tumors > 3 cm maximal p-fossa dimension with brainstem compression: intraoperative monitoring of trigeminal nerve (Cr. N. V), lower cranial nerves (Cr. N. IX, X) and use of SSEPs is not obligatory but should be considered[52]
  - for tumors > 3 cm diameter with symptomatic hydrocephalus: pre-op placement of EVD is optional. A VP shunt should be placed if the hydrocephalus does not resolve post-op[52]

Selection options for intervention

Once treatment is elected (see algorithm above), the type of treatment must be selected.

Comparison of microsurgery vs. radiosurgery (SRS)

1. hearing preservation
   a) for patients with testable preoperative hearing
      - summary: radiosurgery or stereotactic radiation appears to be better at preserving hearing than microsurgery for VS < 2 cm up to 5 years post treatment. The chances of hearing preservation at 10 years is the same with SRS or MS. The difference is minor for tumors < 10 mm and very good preoperative hearing (70% SDS, and 30 dB PTA). The advantage of radiation is more pronounced for larger tumors and greater preoperative hearing loss. Details:
      - SRS: overall, at 2, 5, and 10 years, 50–75%, 50–75%, and 25–50% of the patients maintained their GR hearing class (▶ Table 45.5). Hearing preservation appears to be related to the radiation dose to the cochlea rather than to the tumor itself[57]
      - microsurgery: hearing preservation is significantly related to the tumor size and to the experience of the surgical team. Hearing preservation in Samii's series of 1000 VS[55] improved from 24% in the first 200 cases to 49% in later cases. Hearing preservation in microsurgery has improved with the use of direct cochlear nerve monitoring[58] compared to auditory brainstem responses monitoring only. Hearing preservation in patients with class A, small tumors and direct cochlear nerve monitoring (compound nerve action potential) was 91%.[59] With microsurgery, the durability of the hearing preservation is also excellent with only 15% of patients with class A hearing after surgery, and 33% of patients with class B hearing after surgery slipping one class at 5 years follow-up[60]
2. facial nerve preservation
   a) preservation has been excellent with both microsurgery and radiosurgery
   b) microsurgery: 98.5% overall[61] and 100% in tumors not touching the brainstem. Staged resection has been advocated by some to improve facial nerve preservation in giant VS (> 4–4.5 cm)[62]
   c) radiosurgery: 98% of patients.[63] The incidence of facial neuropathy has significantly decreased since the SRS dose was decreased to 12–13 Gy. Facial neuropathy in the recent series occurred in patients having received 18–20 Gy
3. trigeminal neuropathy (TGN)
   a) a complication classically feared in large tumors especially following SRS
   b) SRS: 7% incidence of TGN (mainly in patients receiving higher doses, i.e., 18 Gy). No patients who received a dose < 13 Gy developed TGN[63]
   c) microsurgery: post-op TGN is not reported in most series
4. tumor control (local control rate (LCR)):
   a) microsurgery: tumor recurrence has been poorly studied. Quoted rates in the literature vary between 0.5% at 6 years[61] and 9.2%[64]
   b) SRS: long term data are lacking with the currently favored dose of 12–14 Gy to the tumor margin. In 68 patients with sporadic VS with median follow-up of 43.5 months[65]:
      - intracanalicular VS: no growth after SRS (9 patients)

- extracanalicular VS: 97% LCR for VS that grew at a rate < 2.5 mm/year before SRS, vs. 69% LCR for VS that grew ≥ 2.5 mm/year before SRS
- 10-18% of patients show swelling ("pseudogrowth")[63,65] following SRS defined as enlargement ≥ 2 mm within 6-12 months that decreased or stabilized in size on follow-up

Vertigo and dizziness

Practice guideline: Balance problems with VS

Data is insufficient to support MS or SRS for balance problems due to VS[66]

For patients with episodic vertigo or balance difficulties as the predominant symptom; also, see points under Selection options for intervention (p. 788):

1. remember: patients with VS are susceptible to other causes of vertigo as well, and patients should undergo ENG and functional balance assessment
2. vertigo that is due to the VS is often self-limited, and improves in 6–8 weeks to a reasonably tolerable level with no treatment (patients may do better with so-called "vestibular rehab")
3. residual dizziness and balance disturbances are common whether stereotactic radiosurgery (SRS) or microsurgery (MS) is used, but are typically less after MS
4. patients' reported vertigo intensity is improved by any treatment versus observation[67]
5. after SRS: a minimum of 5–6 mos, and sometimes up to 18 months may be required to produce beneficial effects. Symptoms are improved more rapidly after MS than with SRS
6. following MS: The severity of dizziness after MS depends on the preoperative vestibular function on the affected side. If the ipsilateral vestibular function is absent preoperatively, then patients will not suffer from dizziness or nausea post-op. If ipsilateral vestibular function is intact pre-op, then patients may be very dizzy and nauseated in particular for the first 24 hrs
7. conclusion:
   a) observation may be the best choice for ≈ 20% of patients ("wait and scan")
   b) when treatment is desired:
      - surgery is the best choice for most VSs producing vertigo
      - SRS may be the right choice for some, especially: elderly patients (> 70 yrs) with other health problems, for recurrence of VS, for intracanalicular tumors or tumors growing < 2 mm/year, and for individual preference

Hydrocephalus

When hydrocephalus is present, it may require separate treatment with a CSF shunt—see Surgical considerations (p. 791)—and may possibly be done at the same time as surgery for the VS (if surgery for the VS is indicated).

45.3.7 Surgical treatment

Practice guidelines for surgical management of vestibular schwannomas

Practice guideline: Surgical management of vestibular schwannomas

For the full guideline, see reference.[66]

Choice of surgical approach or surgical team

- When serviceable hearing is present: data is insufficient to recommend either middle fossa (MF) or retrosigmoid (RS) approach over the other for complete resection and facial nerve (FN) preservation[66]
- When serviceable hearing is not present: data is insufficient to recommend either the RS or translabyrinthine (TL) approach over the other for GTR and FN preservation[66]
- Outcome data is insufficient to recommend a multispecialty team (neurosurgeon and neurotologist) over either specialty working alone[66]

Microsurgery (MS) for small VS

- Data is insufficient to support a firm recommendation that surgery should be the primary treatment for intracanalicular VS < 1.5 cm[66]
- Level III[66]: hearing preservation surgery may be attempted via the MF or RS approach for VS < 1.5 cm with good pre-op hearing

Microsurgery (MS) for VS in patients with neurofibromatosis type 2 (NF2)

- There is insufficient data that MS should be the initial treatment for VS in NF2[66]

Miscellaneous information regarding microsurgery (MS) for VS

- There is insufficient data that subtotal resection followed by SRS provides comparable hearing and FN preservation to patients having GTR[66]
- Level III[66]: trigeminal neuralgia with VS is better relieved with MS than with SRS
- Level III[66]: patients should be counseled that MS after SRS has an increased likelihood of STR and decreased FN function
- Level III[68]: FN monitoring is recommended during MS to improve long-term FN function (strong Delphi consensus[52])
- Level III[68]: favorable intraoperative FN response is a reliable predictor of good long-term FN outcome, but a poor response in the presence of an anatomically intact FN does not reliably predict long-term FN function & cannot be used to direct decisions for early reinnervation procedures
- Level III[68]: intraoperative VIII nerve monitoring should be used when hearing preservation surgery is a goal. Update: auditory brainstem reflexes (ABRs) should be utilized, and direct cochlear nerve action potential monitoring should be considered when feasible (strong Delphi consensus[52])

Abbreviations: FN = facial nerve; GTR = gross total resection; MF = middle fossa; MS = microsurgery; RS = retrosigmoid; STR = subtotal resection; TL = translabyrinthine approach.

Approaches

General information

Three basic surgical approaches:

1. those with possibility of hearing preservation
   a) middle fossa (MF): poor access to posterior fossa (see below)
   b) retrosigmoid (RS) (see below) AKA retrosigmoid-transmeatal approach
2. translabyrinthine (TL): non-hearing preserving (see below)

Excellent results have been reported with each of these approaches. These guidelines assume that the surgical team is comfortable with all three approaches.

Decision algorithm for approach

The choice of approach is dictated by hearing salvageability and tumor size as follows:

1. salvageable hearing (▶ Table 45.10 for definition and guidelines)
   a) if tumor is intracanalicular (no extension beyond a few mm into the posterior fossa (CPA); note: differences of opinion exist regarding how much tumor in the CPA can be removed via MF): use the middle fossa approach. Note: some authors exclusively use the retrosigmoid approach for hearing preservation even for these tumors with excellent results
   b) if tumor extends > few mm into the posterior fossa: use the retrosigmoid approach (it is generally accepted that the cisternal part of the tumor is not well exposed by the middle fossa approach, especially regarding the ability to dissect tumor off the nerves)
2. non salvageable hearing (see ▶ Table 45.10 for definition and guidelines)
   a) use translabyrinthine approach or retrosigmoid approach
   b) either can be used irrespective of tumor size. Surgical team preference is the main deciding factor. Some influencing aspects:
      - a young patient with no cerebellar atrophy might favor a translab approach
      - an anteriorly situated sigmoid sinus and/or a high riding jugular bulb restrict the working space in the translab approach, and might favor a retrosigmoid approach

Table 45.10 Hearing salvageability

Serviceable and unsalvageable hearing
Definition of serviceable hearing
A generous definition of serviceable hearing: PTA < 50 dB and SDS > 50%[a]
Unsalvageable hearing
Serviceable hearing is *unlikely* to be preserved post-op when 1. pre-op SDS < 75% 2. or pre-op PTA loss > 25 dB 3. or pre-op BAER has abnormal wave morphology 4. or tumor > 2–2.5 cm diameter
[a]see also other definitions of serviceable hearing (p. 781)

Surgical considerations

General information

The first surgical removal of a vestibular schwannoma was performed over a century ago in 1894.[69]

The facial nerve is pushed forward by the tumor in ≈ 75% of cases (range: 50–80%), but may occasionally be pushed rostrally, less often inferiorly, and rarely posteriorly. It may even continue to function while it is flattened to a mere ribbon on the tumor capsule surface.

Anesthesia with minimal muscle relaxants allows intra-op seventh nerve monitoring. In only ≈ 10% of large tumors is the cochlear nerve a separate band on the tumor capsule, in the remainder it is incorporated into the tumor.

Although total excision of tumor is usually the goal of surgery, facial nerve preservation must take precedence over degree of resection. Near total resection (very small sliver of tumor left on the facial nerve) or subtotal resection are all excellent options if the tumor is tightly adherent to the facial nerve or the brainstem. Both have excellent long term tumor control rate with either observation or post-op radiation.

If hydrocephalus is present, historically standard practice was to place a CSF shunt and wait ≈ 2 weeks before the definitive operation.[70] While still acceptable, this is less commonly done at present, and shunting or EVD is often performed under the same anesthesia.

Large tumors may be approached by a staged surgical approach to debulk tumor and preserve facial nerve, or a planned subtotal resection followed by radiation. For tumors > 3 cm, such an approach seems to lead to improved results of facial nerve function.[71]

The extra anesthesia time involved in translab approach may be detrimental in the elderly.

Middle fossa approach

- indications:
  a) hearing preservation
  b) laterally placed tumors
  c) small tumors (usually < 2.5 cm)
- pros:
  a) allows drilling and exposure of the IAC all the way to the geniculate ganglion (good for laterally placed tumors)
  b) basically an extradural subtemporal operation
- cons:
  a) potential damage to temporal lobe with risk of seizures
  b) facial nerve is the most superficial nerve in this exposure and therefore the surgeon works "around" the facial nerve (possibility of injury)
- technique summary
  a) lumbar drain
  b) usually straight incision, starting in front of the tragus, extending cephalad for 6 cm, held open with a self-retaining retractor
  c) the temporalis muscle is incised vertically (along the muscle fibers) along the most posterior aspect of the exposure and is reflected anteriorly
  d) craniotomy: 4 cm × 3 cm
  e) elevate the middle fossa dura, section the middle meningeal artery. Identify and preserve the greater superficial petrosal nerve (GSPN), arcuate eminence, V3, and true edge of the petrous bone (the false edge is the groove occupied by the superior petrosal sinus)

f) drill and expose the internal auditory canal all the way to Bill's bar (for tumors extending laterally)
g) localize the facial nerve with the nerve stimulator
h) open the IAC dura along the main axis of the IAC, avoiding VII
i) identify the vestibular, cochlear, and facial nerves
j) dissect the tumor off the nerves

Translabyrinthine approach

Often preferred by neurotologists.

1. pros & cons: See ▶ Table 45.11
2. technique summary
   a) position: supine head rotated to contralateral side, can be done either with pins or doughnut if it is anticipated that no retractors will be used
   b) prep the abdomen for fat graft (almost always used)
   c) skin incision should be tailored to the location of the sigmoid sinus (observe location of the sigmoid sinus and pinna of the ear on the pre-op MRI). Usually smaller opening than retrosigmoid approach
      - does not require a craniotomy. For large tumors requiring an "extended translab," 1–2 cm of retrosigmoid dura should be exposed during the mastoidectomy to allow for retraction of the sigmoid sinus
      - dural opening along the IAC after identification of VII with stimulator
      - for large tumor: section the superior petrosal sinus and section the tentorium to gain better intradural exposure
      - closure requires fat graft

Table 45.11 Pros & cons of translabyrinthine approach

Disadvantages	Advantages
• sacrifices hearing (acceptable when hearing is already non-functional or unlikely to be spared by other approach) • may take longer than retrosigmoid approach • possibly higher rate of post-op CSF leak	• early identification of VII may result in higher preservation rate • less risk to cerebellum and lower cranial nerves • patients do not get as "ill" from blood in cisterna magna, etc. (essentially an extracranial approach) • less trauma to musculature ∴ less H/A than retrosigmoid

Booking the case: Translabyrinthine approach for vestibular schwannoma

Also see defaults & disclaimers (p. 25).

1. position: supine with shoulder roll
2. equipment:
   a) microscope
   b) high speed drill
   c) ultrasonic aspirator
3. some surgeons work with neurotologist to assist with the IAC and for follow-up
4. neuromonitoring: facial EMG (does not require EEG tech), SSEPs for tumors involving the brainstem (requires EEG tech)
5. post-op: ICU
6. consent (in lay terms for the patient—not all-inclusive):
   a) procedure: surgery through an incision behind the ear to remove a tumor growing inside the skull on the nerve to the ear. Possible need for post-op lumbar drain. Fat graft (≈ always used)
   b) alternatives: nonsurgical management with follow-up MRIs, other surgical approaches, radiation (stereotactic radiosurgery)
   c) complications: CSF leak with possible meningitis, loss of hearing in ipsilateral ear (if not already lost), paralysis of facial muscles on the side of surgery with possible need for surgical procedures to help correct (correction is often far from perfect), facial numbness, post-op balance difficulties/vertigo, brainstem injury with stroke

Retrosigmoid approach

AKA posterior fossa, AKA suboccipital approach.[72,73]

- pros:
  - a) familiar to most neurosurgeons ∴ often preferred by neurosurgeons
  - b) quick access to the tumor
  - c) hearing preservation possible
  - d) NOTE: this approach is very versatile. Samii[55] resected all his acoustic tumors via a retrosigmoid approach; he achieved a significant amount of brain relaxation and improved exposure by using in the sitting position, which is generally not used in the U.S. because of associated complications (p. 1737)
- cons:
  - a) cerebellar retraction: not a problem for tumors < 4 cm, provided the craniotomy is sufficiently lateral and the cisterna magna and the CP angle cistern has been opened
  - b) headaches: it has been suggested that headaches are more common following retrosigmoid craniotomy than after translabyrinthine craniotomy. Postulated mechanisms: purely extradural drilling in translab with no bone dust in subarachnoid space. More anterior skin incision in translab and less disruption of the suboccipital musculature and greater occipital nerve

Booking the case: Retrosigmoid craniotomy for vestibular schwannoma

Also see defaults & disclaimers (p. 25).

1. position: lateral decubitus with tumor side up
2. equipment:
   - a) microscope
   - b) ultrasonic aspirator
   - c) image guided navigation system (if used) (may be helpful for placing skin incision and craniotomy more than for tumor localization)
3. some surgeons work with neurotologist to assist with the IAC and for follow-up
4. neuromonitoring: facial EMG (does not require EEG tech), BAERS, near field monitoring (CNAP: compound nerve action potential)
5. post-op: ICU
6. consent (in lay terms for the patient—not all-inclusive):
   - a) procedure: surgery through an incision behind the ear to remove a tumor growing inside the skull on the nerve to the ear. Possible need for post-op lumbar drain. Possible fat graft (optional)
   - b) alternatives: nonsurgical management with follow-up MRIs, other surgical approaches, radiation (stereotactic radiosurgery)
   - c) complications: CSF leak with possible meningitis, loss of hearing in ipsilateral ear (if not already lost), paralysis of facial muscles on the side of surgery with possible need for surgical procedures to help correct (correction is often far from perfect), facial numbness post-op balance difficulties/vertigo, brainstem injury with stroke. Facial numbness (infrequent)

Technique summary

1. position: lateral decubitus with tumor side up, head in pins rotated (might need shoulder roll), zygomatic arch horizontal. 30° elevation of the head is paramount; see Posterior fossa (suboccipital) craniectomy, Lateral oblique position (p. 1738)
2. percutaneous lumbar drain (optional)
3. incision is shaped like the pinna of the ear, 3 finger breaths behind the external auditory canal
4. the craniotomy has to be lateral enough to expose part of the sigmoid and part of the transverse sinuses and to allow a straight line of sight to the lateral end of the IAC
5. to prevent CSF leak, seal all bone edges with bone wax
6. dural opening along the lines of the craniotomy
7. exposure is enhanced by opening the cerebellopontine angle cistern and the cisterna magna under the microscope and draining CSF (20–40 ml of CSF can also be drained via a lumbar subarachnoid catheter)
8. the petrosal vein is often sacrificed at the beginning of the procedure to allow the cerebellum to relax and fall back and to avoid tearing off the transverse sinus. Be careful not to coagulate the SCA that often runs with the petrosal vein

9. using the facial nerve stimulator, the posterior aspect of the tumor is inspected to make sure the facial nerve has not been pushed posteriorly
10. the thin layer of arachnoid that covers most tumors is identified. Vessels within the arachnoid may contribute to cochlear function and may be preserved by keeping them with the arachnoid
11. the plane between tumor and cerebellum may be followed to the brainstem, and occasionally to the VII nerve (this plane is harder to follow once bleeding from tumor debulking occurs)
12. to help locate the origin of the VII nerve at the brainstem, see ▶ Table 45.12 and CPA anatomy in ▶ Fig. 1.11
13. the posterolateral tumor capsule is opened, and internal decompression is performed. The tumor is collapsed inward and the capsule is kept intact and is rolled laterally off of VII and is eventually removed. The most difficult area to separate VII from tumor is just proximal to the entrance to the porus acusticus. A general recommendation is to accept a subtotal or near total resection to preserve anatomic continuity of the facial nerve in cases where it is identified by stimulation but because it is so flattened it cannot be seen as a separate structure on the surface of the tumor.
14. after the extracanalicular portion of tumor is removed, the dura over the IAC is incised, and the IAC is drilled open and tumor is removed from this portion. To preserve hearing, the bony labyrinth must not be violated. The posterior semicircular canal (SCC) is the most vulnerable structure (▶ Fig. 45.10). The vestibule of the SCCs is also at risk but is less likely to be entered. The maximal amount of temporal bone drilling that can be accomplished without entering the posterior SCC can be determined from the pre-op CT. The operculum of the temporal bone is a small step-off palpable with a nerve hook posteriorly from the porus acusticus. It marks the location of the vestibular aqueduct and is a good landmark for the posterior extent of the drilling in the retrosigmoid exposure of the IAC. Measuring the distance from the IAC to the posterior semicircular canal on a pre-op CT and measuring the thickness of the bone overlying the posterior semicircular canal are recommended for safe exposure of the IAC, in particular for hearing preservation. However, opening the labyrinth cannot always be avoided; and any opening should be plugged with bonewax or muscle.[74] If the facial nerve is not intact and is not going to be grafted, then the IAC should be plugged, e.g., by bone wax covered with a small piece of hammered muscle (hammering makes the muscle sticky by activating extrinsic clotting factors) and Gelfoam®.

Table 45.12 Aids in localizing VII nerve origin[76]

- VII nerve originates in the pontomedullary sulcus near the lateral end of the sulcus, 1–2 mm anterior to the VIII nerve
- the pontomedullary sulcus ends just medial to the foramen of Luschka (extending from the lateral recess of the IV ventricle, ▶ Fig. 1.11)
- a tuft of choroid plexus usually extends out of the foramen of Luschka on the posterior surface of IX and X nerve, just inferior to the origin of VII
- the flocculus of the cerebellum projects from the lateral recess into the CPA just posterior to the origin of VII and VIII
- VII origin is 4 mm cephalad and 2 mm anterior to that of the IX nerve

NB: *large tumors*: in some large tumors, the capsule may be adherent to the brainstem and so portions of tumor must be left; recurrence rate among these is ≈ 10–20%.[75] Large tumors may also involve V superiorly (sometimes VII is pushed up against V), and inferiorly may involve IX, X, and XI. The lower cranial nerves can usually be spared by dissecting them off of the tumor capsule, and protecting them with cottonoids.

Post-op care and care for complications

Practice guideline

Practice guideline: Perioperative nimodipine for VS surgery

Level III[77]: perioperative nimodipine (possibly with the addition of hydroxyethyl starch) should be considered to improve facial nerve functional outcome and may help with hearing outcome following microsurgery

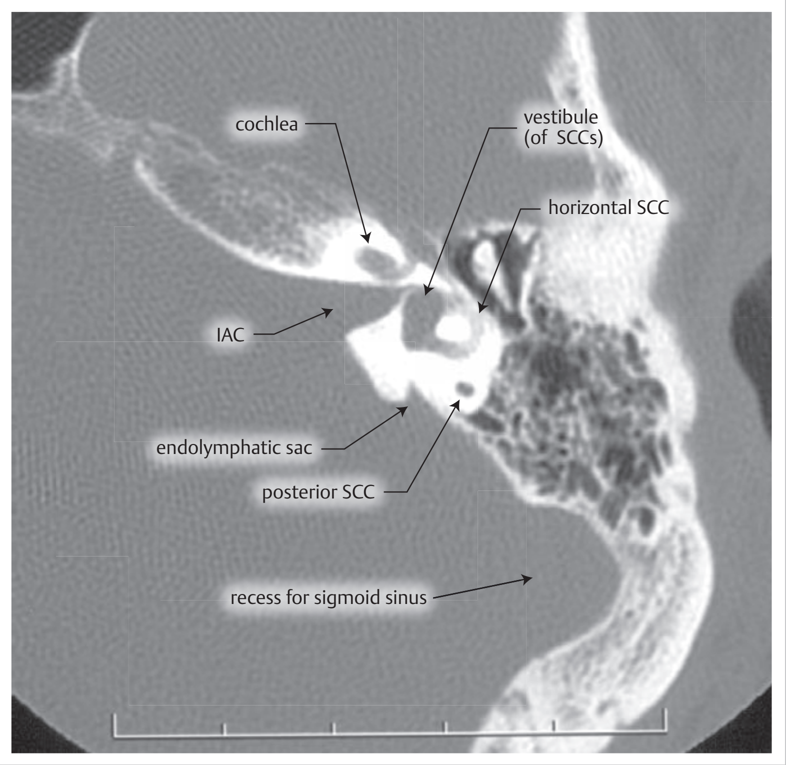

Fig. 45.10 Temporal bone structures. Image: CT scan, axial slice through left petrous bone with bone windows. Provided courtesy of Chris Danner, MD.

Cranial nerve and brainstem dysfunction

Facial nerve (VII)

If eye closure is impaired due to VII dysfunction: ℞ natural tears 2 gtts to affected eye q 2 hrs and PRN. Apply Lacrilube® to affected eye and tape it shut q hs. If the eye is also insensate from Cr. N. V impairment, the eye is at risk of exposure and trophic keratitis and immediate consultation with ophthalmology for emergency tarsorrhaphy is indicated. Early tarsorrhaphy should also be considered If there is complete VII palsy with little chance of early recovery.

Facial re-animation (e.g., hypoglossal-facial anastamosis) is performed after 1–2 months if VII was divided, or if no function returns after 1 year with an anatomically intact nerve.

Vestibular nerve (VIII)

Vestibular dysfunction is common post-op, nausea and vomiting due to this (and also intracranial air) is common. Balance difficulties due to this clear rapidly; however, ataxia from brainstem dysfunction may have a permanent component.

Lower cranial nerves

The combination of IX, X, and XII dysfunction creates swallowing difficulties and creates a risk of aspiration.

Brainstem dysfunction

Brainstem dysfunction may occur from dissection of tumor off of the brainstem. This may produce ataxia, contralateral paresthesias in the body. Although there may be improvement, once present, there is often some permanent residual.

CSF fistula

Also, see CSF fistula (cranial) (p. 415) for general information. CSF fistula may develop through the skin incision, the ear (CSF otorrhea) through a ruptured tympanic membrane, or via the eustachian tube and then either through the nose (rhinorrhea) or down the back of the throat.

Rhinorrhea may occur through any of the following routes (circled numbers in ▶ Fig. 45.11):

- ① via the apical cells to the tympanic cavity (TC) or eustachian tube (the most common path)
- entry into the bony labyrinth—reaching the middle ear would require rupture (e.g., of the oval window by overpacking bone wax into the labyrinth)
  - ② through the vestibule of the horizontal semicircular canal (SCC)
  - ③ through the posterior SCC (the posterior SCC is the most common area that is entered by drilling)
- ④ follows the perilabyrinthine cells and tracts to the mastoid antrum
- ⑤ through the mastoid air cells surgically exposed at the craniotomy site

Most leaks are diagnosed within 1 week of surgery, although one presented 4 years post-op.[78] They appear to be more common with more lateral unroofing of the IAC.[78] Meningitis complicates a CSF leak in 5–25% of cases, and usually develops within days of the onset of leak.[78] Hydrocephalus may promote the development of a CSF fistula.

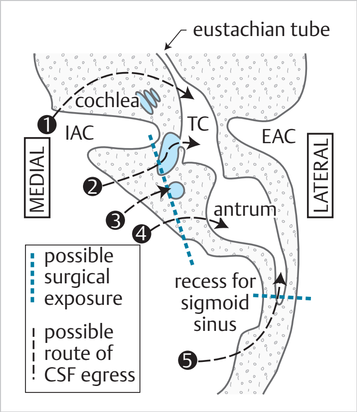

Fig. 45.11 Possible routes for CSF rhinorrhea following vestibular schwannoma surgery (see text). Image: schematic axial slice through right petrous bone. Adapted from Surgical Neurology, Vol. 43, Nutik S L, Korol H W, Cerebrospinal Fluid Leak After Acoustic Neuroma Surgery, 553–7, 1995, with permission from Elsevier Science.

Treatment: 25–35% of leaks stop spontaneously (one series reported 80%).[78] Treatment options include:

1. surgical treatment: in general, postoperative CSF leak (including rhinorrhea) is best addressed with immediate surgical re-exploration. Non-surgical measures (see following items) may be used to temporize
   a) in the case of a translabyrinthine approach with absent ipsilateral hearing: to treat rhinorrhea, pack and permanently close the Eustachian tube via a trans tympanic membrane approach. This is very effective and avoids re-opening the surgical incision and removing the previously placed fat graft.
   b) if hearing is preserved (which excludes translab), every effort should be made to preserve the Eustachian tube function to preserve middle ear function. Re-explore the surgical field, re-wax the aircells and place additional fat graft, fascia, pericranium, or other sealant over the exposed aircells. This aggressive management is the most definitive and rapid treatment, and avoids prolonged bed rest required by placing a lumbar drain and trying to control the leak in a conservative way
2. non-surgical: may be used to temporize, but early surgical treatment is recommended
   a) evaluate for infection, which is often associated with CSF leak
   b) elevate HOB

c) for leaks through the incision, reinforcement with additional sutues may be attempted
d) a percutaneous lumbar subarachnoid drain may be tried,[79,80] although some debate its efficacy,[73] and there is a theoretical risk of drawing bacteria into the CNS
e) placement of EVD

3. a CSF leak may be an indication of altered CSF hydrodynamics. Most of these patients demonstrate frank ventriculomegaly (hydrocephalus). In some patients the leak may function as a pressure relief valve and thereby ameliorate the ventriculomegaly (i.e., there would be hydrocephalus if there wasn't a leak). Adjunctive CSF shunting is usually also necessary or the repair will be more likely to fail

Outcome and follow-up

Complete surgical removal was reported in 97–99% of cases.[81]

Surgical morbidity and mortality

Also see Post-op considerations for p-fossa cranis (p. 1744). Estimated frequency of some complications[82]: the most common complication is CSF leakage in 4–27%[78] (see above), meningitis in 5.7%, stroke in 0.7%, subsequent requirement for CSF shunt (for hydrocephalus or to treat leak) in 6.5%.

The mortality rate is ≈ 1% at specialized centers.[55,81,83]

Cranial nerve dysfunction

▶ Table 45.13 shows statistics of VII and VIII cranial nerve preservation following suboccipital removal of VSs in several combined groups of patients. For more details, see below.

Post-radiation cranial neuropathies generally appear 6–18 months following stereotactic radiosurgery (SRS),[85] and since more than half of these resolve within 3–6 months after the onset, the recommendation is to treat these with a course of corticosteroids.

▶ **Facial nerve (VII).** See ▶ Table 45.3 for the House and Brackmann grading scale. Grades 1–3 are associated with acceptable function. Facial nerve preservation is related to tumor size.

Surgery: With the use of modern facial nerve monitoring techniques, anatomical integrity of the facial nerve can be achieved in > 90% even for very large tumors and in close to 99% in medium-sized tumors.[86] In cases where the nerve is so flattened that the tumor has to be left over the nerve to preserve its anatomical integrity, functional outcome of the facial nerve is nevertheless lower, especially with larger tumors. Excellent outcome (HB grade I-III) was only achieved in 75% of the patients with large tumors and 91% in medium-sized tumors.

SRS for tumors ≤ 3 cm diameter: With modern SRS dosimetry (12–13 Gy for patients with serviceable hearing and 13–14 Gy for patients with non-serviceable hearing), the incidence of new facial nerve weakness was 4%.[87]

Table 45.13 Cranial nerve preservation in retrosigmoid removal of VSs[a]

Size of tumor	Preserved function	
	VII nerve	VIII nerve
< 1 cm	95–100%	57%
1–2 cm	80–92%	33%
> 2 cm	50–76%	6%

[a]series of 135 VSs[84 (p 729)] and other sources[75 (p 3337),81]

▶ **Vestibulo-acoustic nerve (VIII).** Patients with unilateral VS and Class I or II hearing (▶ Table 45.5) comprised ≈ 12% of cases in a large series.[88] Preservation of hearing is critically dependent on tumor size, with little chance of preservation with tumors > 1–1.5 cm diameter. Chances of preserving hearing may possibly be improved by intraoperative brainstem auditory evoked potential monitoring.[89] In centers treating large numbers of VSs, hearing *preservation* rates of 35–71% can be achieved with tumors < 1.5 cm[88,90] (although a range of 14–48% may be more realistic[91]). Hearing may rarely be improved post-op.[92]

SRS: for tumors ≤ 3 cm diameter,[93] hearing was preserved in 26% of 65 cases with pre-op pure tone threshold < 90 dB. Hearing loss has been correlated with increase in tumor size.[94] NB: there is a *high* rate of hearing loss at 1 year. SRT: useful hearing was preserved in 93%.[95]

Vestibular nerve function is rarely normal post-op. Attempts at "vestibular" sparing surgery have shown no better results than surgery not specifically addressing this issue. Most patients with unilateral loss of vestibular nerve function will learn to compensate to a significant degree with input from the contralateral side, if normal. Patients with ataxia as a result of brainstem injury from the tumor or the surgery will have more difficulties post-op. Some patients will seem to do well initially post-op with respect to vestibular nerve function, only to undergo a delayed deterioration several months post-op. These cases likely represent aberrant regeneration of the vestibular nerve fibers and may be extremely difficult to manage. Some experts advocate cutting the vestibular nerve, as for Meniere disease (p. 604).

▶ **Trigeminal nerve (V).** Postoperative trigeminal nerve symptoms occur transiently in 22% and permanently in 11% following microsurgery, similar to the results of SRS.[96] New facial numbness occurred in 2% with SRT.[95]

▶ **Lower cranial nerves.** Injuries to IX, X, and XI occur infrequently following surgery on large tumors that distort the nerves and displace them inferiorly against the occipital bone.

Recurrence

Following microsurgery (MS)

Recurrence is highly dependent on extent of removal. However, recurrence can develop in tumors that were apparently totally removed, or when subtotal resection was performed. This can occur many years after treatment. Tumor progression rate following subtotal resection is ≈ 20%.[91] All patients should be followed with imaging (CT or MRI). In older series with up to 15 yrs follow-up, local control rate (LCR) after "total resection" is ≈ 94%. More recent series with MRI follow-up indicate recurrence rates of 7–11% (3–16 yrs follow-up).[91]

Use of EBRT

EBRT may improve LCR in incompletely resected tumors as shown in ▶ Table 45.14 (note: with the long survival expected with benign tumors, post-XRT complications may occur).

Table 45.14 Local control rates of surgery vs. surgery + EBRT for VSs[97]

Extent of surgical removal	Local control rate (LCR)	
	Surgery	Surgery + EBRT[a]
gross total	60/62 (97%)	no data
near total (90–99%)	14/15 (93%)	2/2 (100%)
subtotal (< 90%)	7/13 (54%)	17/20 (85%)[a]
biopsy only	no data	3/3 (100%)

[a]with doses < 45 Gy, LCR was 33%; with > 45 Gy, LCR was 94%

Microsurgery vs. SRS

In a non-randomized retrospective study[96] of VSs < 3 cm dia, the *short-term* LCR (median 24 mos follow-up) was 97% for microsurgery vs. 94% for stereotactic radiosurgery (SRS). However, for benign tumors, long-term follow-up is critical (possibly 5–10 years[85]), and this study *suggests* that the long-term LCR will be better for MS than SRS. SRS studies with long-term follow-up[98] are not directly comparable because in the cases with longest follow-up, higher radiation doses were used with a resultant higher incidence of radiation complications, and an anticipated better LCR.

Initially there may be temporary enlargement of the tumor accompanied by loss of central contrast enhancement following SRS in ≈ 5% of patients[99] (with up to 2% of patients showing actual initial tumor growth), and so the need for further treatment after SRS should be postponed until there is evidence of sustained growth.[100] Surgery should therefore be avoided during the interval from 6 to 18 months after SRS because this is the time of maximum damage from the radiation.[100]

Although the numbers are small, the rate of VII nerve injury may be higher in patients undergoing MS following SRS failure to achieve LCR compared to cases where microsurgery was the initial procedure[101,102]; however, this has been disputed.[100] Lastly, there is a potential for malignant transformation of VSs following SRS, including triton tumors[103,104] (malignant neoplasms with rhabdoid features) or the induction of skull base tumors (which has been reported with external beam radiation[105]), as well as the risk of late arterial occlusion (the AICA lies near the surface of VSs), any of which may occur many years later. The observed malignant transformation rate is 0.3% and the annual incidence of malignant transformation is 0.02%.[106]

Practice guideline: Malignant transformation of VS after SRS

Level III[48]: patients should be informed that there is a minimal risk of malignant transformation of VS after SRS

Treatment for recurrence following microsurgery

Repeat surgery for recurrent VS is an option. One series of 23 patients[107] showed that 6 of 10 patients with moderate or normal VII function maintained at least moderate function after reoperation, 3 patients had increased ataxia, and 1 patient had a cerebellar hematoma. SRS offers a safe and effective long-term management strategy for residual or retained VS after MS.[108] Using SRS for recurrent VSs resulted in progression-free survival rate of 97% at 3 years, 95% at 5 years, and 90% at 10 years. Among patients with any facial dysfunction (▶ Table 45.3, HB II-VI) at the time of recurrence or progression, 19% had improvement after SRS, and 5.5% with some facial function (HB I-V) developed more facial weakness. Among patients with trigeminal neuropathy, 20% had improvement, 5.8% developed or had worsened trigeminal neuropathy after SRS.

Practice guideline: Retreatment with SRS after SRS

Level III[48]: SRS is safe & effective to re-treat patients with VS progression after initial SRS

Hydrocephalus

May occur following treatment (MS or SRS) for VS, and may even occur years later. The increased CSF pressure may also predispose to development of a CSF fistula.

Quality of life

Being diagnosed with a VS creates anxiety and leads to a temporary reduction in quality of life (QoL). However, once a treatment modality is chosen, observational management for amenable tumors produced the highest QoL.[109]

Patients undergoing SRS or observation report a better total Penn Acoustic Neuroma Quality of Life (PANQOL) score and higher PANQOL facial, balance, and pain subdomain scores than those undergoing microsurgical resection. However, the differences in health related QOL outcomes following SRS, observation, and microsurgical resection are small.[110]

Long term QoL in patients with VS $<$ than 3 cm in diameter was higher in those having gross total resection (GTR) than those with less than GTR despite having similar rates of facial nerve and hearing preservation. This may be due to psychological factors. Notwithstanding, functional preservation should be prioritized.

46 Meningiomas (Intracranial)

46.1 General information

Meningiomas are a group of tumors that are believed to originate in meningothelial cells of the arachnoid membrane. They may be intracranial (the most common location), intraorbital, or intraspinal (p. 981).

46.2 Meningioma tumor types

46.2.1 Meningioma (WHO grade 1, 2 or 3)

General information

Key concepts

- slow growing, extra-axial tumor, usually benign, arise from arachnoid (not dura)
- imaging (MRI or CT): classically broad-based attachment on dura often with dural tail, typically enhance densely, hyperostosis of adjacent bone is common
- MRI: isointense on T1WI, hypointense on T2WI
- 32% of incidentally discovered meningiomas do not grow over 3 years follow-up
- surgical indications: documented growth on serial imaging, symptoms referable to the lesion that are not satisfactorily controlled medically, edema (low density on CT, high signal on T2 MRI) changes in adjacent brain
- most (but not all) are cured if completely removed, which is not always possible
- most commonly located along falx, convexity, or sphenoid bone
- frequently calcified: classic histological finding with this are psammoma bodies

Meningiomas are the most common primary intracranial tumors in adults, representing 36.4% of CNS tumors.[1] They comprise 54.5% of non-malignant tumors.[2] They are usually slow growing, circumscribed (non-infiltrating), benign lesions. About 10% are histologically malignant and/or rapidly growing. Meningiomas arise from arachnoid cap cells (meningothelial cells) of the arachnoid layer (not dura). They can be multiple in up to 8% of cases,[3] which is more common in neurofibromatosis. Occasionally meningiomas form a diffuse sheet of tumor (**meningioma en plaque**).

They may occur anywhere that arachnoid cells are found (between brain and skull, within ventricles, intraorbital, and along the spinal cord). Ectopic meningiomas may arise within the bone of the skull (primary intraosseous meningiomas)[4] and others occur in the subcutaneous tissue with no attachment to the skull.

They are characteristically slow growing. Most are asymptomatic (see below).

Psammoma bodies (from the Greek word for sand) are common in some meningioma subtypes, as well as in other tumors, e.g., prolactinomas, schwannomas, papillary thyroid carcinoma… and some non-neoplastic conditions. They are round, microscopic calcified structures having a concentric laminated (onion-like) appearance. The calcification may be dystrophic, or possibly a tumoricidal defense mechanism.[5] They are eosinophilic, and stain positive for CEA and PAS.

Diagnostic criteria for meningioma

Diagnostic criteria for meningioma are shown in ► Fig. 46.1.[6]

Subtypes

See reference.[6]

There is a wide variety of histological morphology among meningiomas, leading to the 15 subtypes delineatd below. The most common ones are meningothelial, fibrous and transitional. Aggressiveness can vary within each subtype (p. 805), but most are benign WHO CNS5 grade 1. However, the chordoid and clear cell subtypes have been assigned grade 2 because of a higher recurrence rate irrespective of the grading criteria discussed in the following section. Most, but not all, rhabdoid meningiomas are considered grade 3.

Meningioma

▷ ESSENTIAL* ◁

classic histopathological features matching at least one of the meningioma subtypes

OR

suggestive histopathological features combined with biallelic inactivation of *NF2* or other classic drivers of conventional meningioma (*TRAF7, AKT1, KLF4, SMO, PIK3CA*), clear cell meningioma (*SMARCE1*), or rhabdoid meningioma (*BAP1*)

OR

suggestive histopathological features combined with one of the defined DNA methylation classes of meningioma

▷ DESIRABLE ◁

- ► meningeal localization
- ► EMA immunoreactivity
- ► strong and diffuse SSTR2A immunoreactivity
- ► classic copy-number alterations of *NF2*-mutant meningioma, such as monosomy 22/22q in lower-grade meningiomas, with additional losses of 1p, 6, 10q, 14q, and/or 18 in higher-grade meningiomas

* diagnosis frequently requires matching of several criteria

Fig. 46.1 Diagnostic criteria for meningioma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

- **meningothelial meningioma:** syncytia-like lobules of epitheliod cells with some nuclei appearing to have holes and pseudoinclusions. May resemble arachnoid cap cells, which may mimic meningothelial hyperplasia which can be seen adjacent to other tumors, e.g., optic gliomas. Whorls and psammoma bodies are less frequent than in fibrous, transitional, and psammomatous subtypes. More common at the skull base than other subtypes
- **fibrous meningioma:** parallel, storiform, or interlacing fascicles of spindle cells in a collagen-rich matrix. Often found over the convexities. Consistency is more rubbery than meningothelial or transitional
- **transitional meningioma:** contains meningothelial and fibrous morphology as well as transitional features. Whorls and psammoma bodies are frequent. Often found over the convexities
- **psammomatous meningioma:** psammoma bodies predominate over meningioma cells (which may be hard to find), and can overlap to form large calcified masses. Often arises in the thoracic spine of middle-aged to elderly women
- **angiomatous meningioma:** small, often hyalinized blood vessels predominate over meningioma cells (which may be hard to find). Angiomatous areas may be scattered in regions consistent with microcystic or metaplastic subtypes, and can manifest nuclear atypia which meets one of the criteria for a higher grade (see next section). Hypervascular specimens may resemble hemangioblastoma. Often produce cerebral edema out of proportion to their size
- **microcystic meningioma:** cells with thin, elongated processes create microcysts with a cobweb-like background. These microcysts may form radiologically identifiable macrocysts. Most are

benign, but degenerative nuclear atypia meets one of the criteria for a higher grade (see next section). Often produce cerebral edema out of proportion to their size
- **secretory meningioma:** foci of cells with gland-like epithelial differentiation and psammoma bodies. Often produce cerebral edema out of proportion to their size
- **lymphoplasmacyte-rich meningioma:** rare. Mengothelial cells are often dominated by chronic inflammatory infiltrates, which may mimic inflammatory conditions having meningothelial hyperplasia
- **metaplastic meningioma:** focal or diffuse mesenchymal features (including one or more of osseous, cartilaginous, lipomatous, myxoid and xanthomatous tissue) which are of unknown clinical signficance. Features may overlap with angiomatous or microcystic subtypes. Ossification may mimic bone invasion or psammoma bodies of the psammomatous subtype
- **chordoid meningioma** (WHO grade 2): cords or trabeculae of small epitheliod cells in a mucin-rich matrix may resembles a chordoma. Chronic inflammatory infiltrates may be prominent. Typically large supratentorial tumors, with a younger average age of presentation (45 years). A high recurrence rate comparable to aytpical meningiomas has caused assignment of WHO grade 2 to these tumors independent of morphology
- **clear cell meningioma** (WHO grade 2): round to polygonal cells with clear, glycogen-rich cytoplasm and prominent PAS-positive staining embedded in perivascular and interstitial collagen arranged in a patternless or sheet architecture. The collagen may coalesce into large acellular structures. Whorls and psammoma bodies are infrequent. Predilection for the CPA and spine (especially the cauda equina) with a young average age (24 years). A high rate of recurrence and CSF seeding has caused assignment of WHO grade 2 to these tumors independent of morphology
- **rhabdoid meningioma:** defined by the identification of rhabdoid cells (plump cells with eccentric nuclei, open chromatin, macronuclei and conspicuous eosinophilis paranuclear inclusions or whorls or waxy spheres). Rhabdoid features alone may be seen in tumors behaving as WHO grade 1 or 2[7]; however, most are highly proliferative and have other malignant features, which together with a high recurrence and mortality rate supports the designation of WHO grade 3 for most, and justifies close follow-up for all. There may be overlap of histologic and genetic features with the papillary subtype
- **papillary meningioma:** defined by a predominant pattern of thin-walled vessels in a perivascular pseudorosette (pseudopapillary) pattern. These tumors have been reported in children and adults, and are commonly associated with peritumoral edema and bony hyperostosis or lysis. Invasion of brain parenchyma and metastases (primarily to lung) are associated with the papillary growth pattern, but in the absence of other higher grade features, focal papillary growth is insufficient for grade 2 or 3 designation
- **atypical meningioma** (WHO grade 2): a meningioma of intermediate grade with features delineated in ▶ Fig. 46.2, which includes elevated mitotic activity and parenchymal brain invasion (extension along Virchow-Robin spaces does not violate the pia and does not qualify as invasion). Nuclear atypia alone is inadequate to classify as grade 2 as it is often degenerative in nature and does not correlate with outcome. Associated with: male gender, non-skull base location and previous surgery. Recurrence rate is higher following GTR than with grade 1 meningiomas, with further elevation in the presence of bone invasion
- **anaplastic (malignant) meningioma** (WHO grade 3): a meningioma that meets grading criteria shown in ▶ Fig. 46.3, often exhibiting extensive necrosis and potential for brain parenchymal invasion. Comprise 1-3% of meningiomas. Loss of H3 p.K28me3 occurs in 10-20% of anaplastic meningiomas and corelates with shorter OS

Grading meningiomas

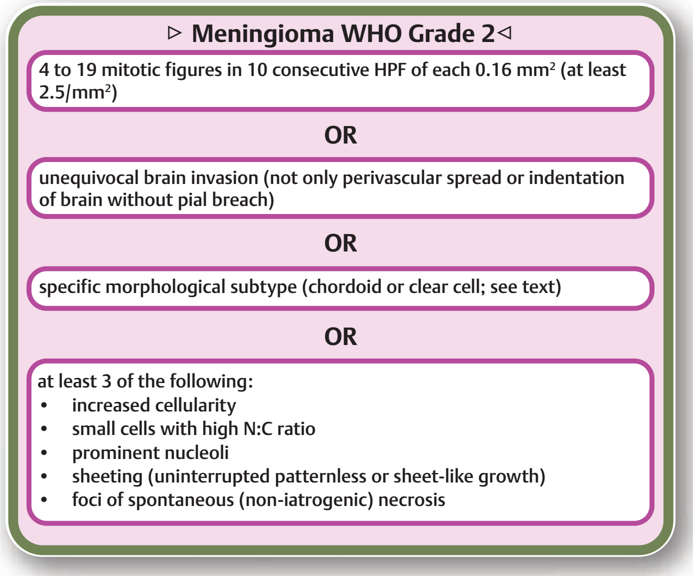
Grading criteria for Grade 2 meningiomas is shown in ▶ Fig. 46.2, and for Grade 3 meningiomas in ▶ Fig. 46.3.[6]

These criteria can be applied across all meningioma subtypes, but the CNS WHO grade 2 criteria must be met for a diagnosis of atypical meningioma, and the CNS WHO grade 3 criteria must be met for a diagnosis of anaplastic (malignant) meningioma.

▶ **Proliferation index.** Due to variation between institutions and observers, it is advised that proliferation indices (e.g., Ki-67 or MIB-1 (p.632)) not be used as the sole discriminant for grading. However, these indices do correlate with prognosis (see ▶ Table 46.1).

Presentation

Symptoms from mass efect or peritumoral edema depend on the location of the tumor. Some specific locations are associated with well-described symptom complexes (see below).



▷ Meningioma WHO Grade 2◁

4 to 19 mitotic figures in 10 consecutive HPF of each 0.16 mm^2 (at least 2.5/mm^2)

OR

unequivocal brain invasion (not only perivascular spread or indentation of brain without pial breach)

OR

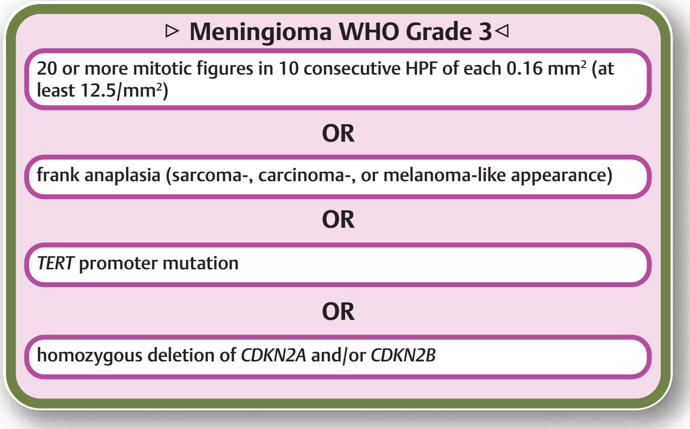
specific morphological subtype (chordoid or clear cell; see text)

OR

at least 3 of the following:

- increased cellularity
- small cells with high N:C ratio
- prominent nucleoli
- sheeting (uninterrupted patternless or sheet-like growth)
- foci of spontaneous (non-iatrogenic) necrosis

Fig. 46.2 Grading criteria for WHO Grade 2 meningioma.



▷ Meningioma WHO Grade 3◁

20 or more mitotic figures in 10 consecutive HPF of each 0.16 mm^2 (at least 12.5/mm^2)

OR

frank anaplasia (sarcoma-, carcinoma-, or melanoma-like appearance)

OR

TERT promoter mutation

OR

homozygous deletion of *CDKN2A* and/or *CDKN2B*

Fig. 46.3 Grading criteria for WHO Grade 3 meningioma.

Table 46.1 Ki-67 proliferation index and recurrence rates in meningiomas[8a]

Description & WHO grade	Mean Ki-67 index[a]	Recurrence rate
common meningioma (WHO grade 1)	0.7%	9%
atypical meningioma (WHO grade 2)	2.1%	29%
anaplastic meningioma (WHO grade 3)	11%	50%

[a]not to be used as sole discriminant for grading (see text)

Seizures may occur with supratentorial meningiomas as a result of irritation of the cerebral cortex. Occasionally patients may feel a mass under their scalp with convexity tumors that invade the bone.

Asymptomatic meningiomas

Meningiomas are the most common primary intracranial tumors, and most remain asymptomatic throughout the patient's life.[9] The routine use of CT and MRI for numerous indications inevitably results in the discovery of incidental (asymptomatic) meningiomas. In a population-based study (the study population was middle class Caucasians and result, may not be generalizable to other demographic groups),[9] incidental meningiomas were seen in 0.9% of MRIs. In another series, 32% of primary brain tumors seen on imaging studies were meningiomas, and 39% of these were asymptomatic.[10] Of 63 cases followed for > 1 year with nonsurgical management, 68% showed no increase in size over an average follow-up of 36.6 mos, whereas 32% increased in size over 28 mos average follow-up.[10] Asymptomatic meningiomas with calcification seen on CT and/or hypointensity on T2WI MRI appeared to have a slower growth rate.[10]

Common locations

▶ Table 46.2 lists common locations. Other locations include: CP angle, clivus, planum sphenoidale and foramen magnum. ≈ 60–70% occur along the falx (including parasagittal), along sphenoid bone (including tuberculum sellae), or over the convexity. Childhood meningiomas are rare, 28% are intraventricular, and the posterior fossa is also a common site. Details on some of these appear in the sections that follow.

Table 46.2 Location of adult meningiomas (series of 336 cases[11])

Location	%
parasagittal	20.8
convexity	15.2
tuberculum sellae	12.8
sphenoidal ridge	11.9
olfactory groove	9.8
falx	8.0
lateral ventricle (intraventricular)	4.2
tentorial	3.6
middle fossa	3.0
orbital	1.2
spinal	1.2
intrasylvian	0.3
extracalvarial	0.3
multiple	0.9

Sphenoid wing (or ridge) meningiomas

Three basic categories[12]:

1. lateral sphenoid wing (or pterional): behavior and treatment are usually similar to convexity meningioma
2. middle third (or alar)
3. medial (clinoidal): tend to encase the ICA and the MCA as well as cranial nerves in the region of the superior orbital fissure and the optic nerve. May compress brainstem. Total removal is often not possible

Olfactory groove meningiomas

Presentation: usually asymptomatic until they are large. Findings may include:

1. Foster Kennedy syndrome (p. 100): can occur when the tumor is asymmetrically situated to one side. Anosmia (patient is usually unaware of this), ipsilateral optic atrophy, contralateral papilledema (from increased ICP)
2. mental status changes: often with frontal lobe findings (apathy, abulia…) mimicking dementia
3. urinary incontinence
4. posteriorly located lesions may compress the optic apparatus causing visual impairment
5. large lesions may compress the fornix and cause short-term memory loss
6. seizure

The morbidity, mortality, and difficulty in achieving total removal increase significantly for tumors > 3 cm in size.[13]

Pre-op MRA, CTA or angiogram may be helpful to assess location of anterior cerebral arteries relative to the tumor. 70–80% of these get the majority of their blood supply from the anterior ethmoidal artery, which is usually not embolized due to risk to ophthalmic artery (and blindness). If there are substantial middle meningeal feeders, these may be embolized, but the benefit tends to be small.

Paarasagittal and falx meningiomas

▶ Fig. 46.4 shows an example of a parafalcine meningioma (PFM).

PFM are grouped based on their location along the AP direction of the SSS as:

- anterior (ethmoidal plate to coronal suture): 44% (in a series of 75 parasagittal meningiomas[14]). Most often present with H/A and mental status changes
- middle (between coronal and lambdoidal sutures): 33%. Most often present as Jacksonian seizure and progressive monoplegia. At the level of the motor strip, a common initial is contralateral foot drop (see ▶ Fig. 1.3 for location of "ankle" area on motor strip)[15]

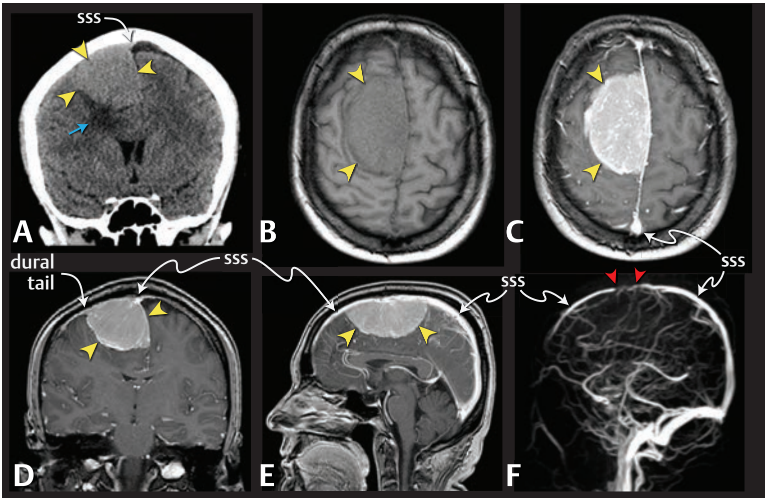


Fig. 46.4 Parafalcine meningioma (*yellow arrowheads*).
Sample images from a 49-year-old woman with a grade 2 (atypical) meningioma presenting with headache and left-sided weakness.
Image: A: coronal noncontrast brain window CT scan. *Blue arrow* denotes edema in the adjacent brain tissue.
B: axial T1 MRI without contrast, C: axial T1 MRI with contrast.
D: coronal T1 MRI with contrast. Note the dural tail which is characteristic of meningioma (but not pathognomonic, nor necessary to diagnose).
E: sagittal T1 MRI with contrast.
F: sagittal contrast MRV. Note the lack of opacification of the superior sagittal sinus between the two *red arrowheads* which is located within the borders of the tumor.
Abreivations: sss = superior sagittal sinus.

- posterior (lambdoidal suture to torcular Herophili): 23%. Most often present with H/A, visual symptoms, focal seizures, or mental status changes

Up to 50% of PFM invade the superior sagittal sinus (SSS). Classification systems for the extent of SSS invasion includes the one by Sindou et al[16] (▶ Fig. 46.5).

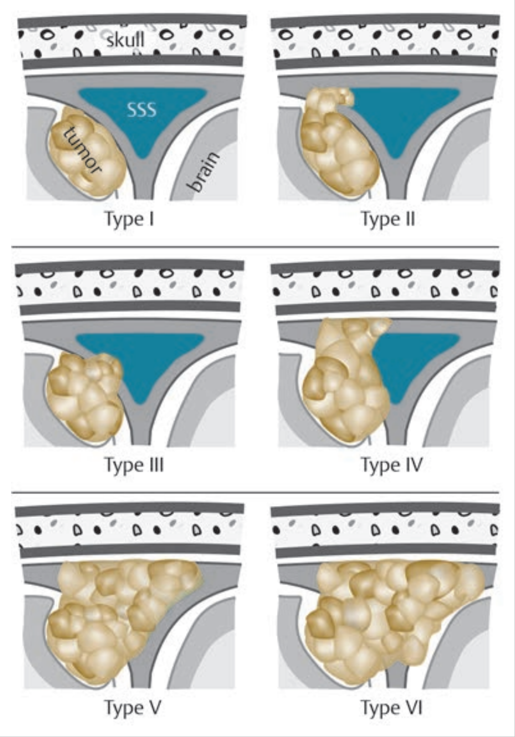

Fig. 46.5 Sindou grading system for meningioma invasion of the superior sagittal sinus.
(Modified from Sindou MP, et al. J Neurosurg. 2006;105:514–525.)
Image: schematic coronal sections through the superior sagittal sinus (SSS).
Type I = attachment to lateral wall of sinus.
Type II = invasion of lateral recess.
Type III = invasion of lateral wall.
Type IV = invasion of lateral wall and roof.
Type V = total sinus occlusion, contralateral wall spared.
Type VI = total sinus occlusion, invasion of all walls.

Planum sphenoidale meningiomas

These uncommon meningiomas arise from the flat horizontal portion of the sphenoid bone (▶ Fig. 46.6) anterior to the chiasmatic sulcus (the depression in the posterior part of the anterior cranial fossa where the optic chiasm perches). An example is shown in ▶ Fig. 46.7. With large meningiomas arising from the floor of the frontal fossa, it may not be possible to differentiate planum sphenoidale from olfactory groove meningiomas.

Tuberculum sellae meningiomas (TSM)

The site of origin of these tumors is only about 2 cm posterior to that of olfactory groove meningiomas.[13] The tuberculum sellae is the bony elevation between the chiasmatic sulcus and the sella turcica (see ▶ Fig. 46.6). By definition, the limbus sphenoidale (which is the anterior margin of the chiasmatic sulcus) is the demarcation between the anterior and middle cranial fossa. Therefore these tumors originate in the middle fossa (unlike planum sphenoidale meningiomas which are in the anterior fossa).

TSMs are notorious for producing visual loss (chiasmal syndrome = primary optic atrophy + bitemporal hemianopsia; see ▶ Fig. 33.2). When a TSM grows posteriorly into the sella turcica it may be mistaken for a pituitary macroadenoma (see ▶ Fig. 99.3 for MRI and differentiating features).

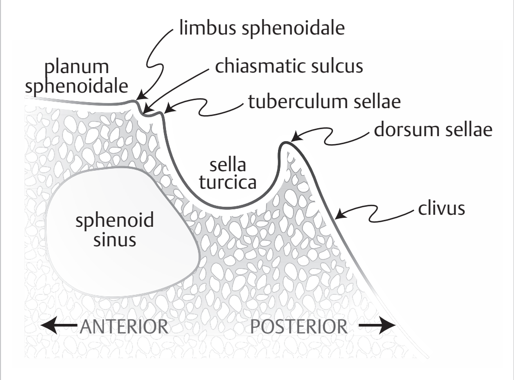

Fig. 46.6 Anatomic locations of planum sphenoidale and tuberculum sellae. The olfactory groove (not shown) is located in the floor of the frontal fossa immediately anterior to the planum sphenoidale.
Image: schematic sagittal section through the sella turcica.

Intraventricular meningiomas

Most are located in the atrium of the lateral ventricle (▶ Fig. 46.8). See also differential diagnosis for intraventricular lesions (p. 1667).

Foramen magnum meningiomas

As with any foramen magnum (FM) lesion (p. 1649); the neurologic symptoms and signs can be very confusing and often do not initially suggest a tumor in this location.

In the French Cooperative Study of 106 FM meningiomas,[17] 31% arose from the anterior lip, 56% were lateral, and 13% arose from the posterior lip of the FM. Most are intradural, but they can be extradural or a combination (the latter 2 have a lateral origin and are often invasive, which makes total removal more difficult).[18] They may be above, below, or on both sides of the vertebral artery.[18]

Epidemiology

▶ **Risk factors**

- ionizing radiation (typically in doses used for radiation therapy) is the only established environmental risk factor,[19] with higher risk in patients exposed as children (e.g., in treating leukemia). There appears to be genetic susceptibility to developing XRT induced meningiomas[20]
- the higher incidence in females and the increased risk in postmenopausal women receiving hormonal replacement therapy (HRT)[21] suggests a hormonal influence
- neurofibromatosis type 1 (NF1) (p. 638) or neurofibromatosis type 2 (NF2) (p. 640)

▶ **Genetics.** 50-60% of WHO grade 1 meningiomas have mutations of the NF2 tumor suppressor gene on chromosome 22q12.2 (which codes for merlin (p. 640)).[22]

Genetic mutations tend to be location dependent: convexity meningiomas and most spinal meningiomas harbor a 22q deletion and/or *NF2* mutation, skull base lesions carry *AKT1, TRAF7, SMO* and/or *PIK3CA* mutations.

▶ **General epidemiology.** As many as 3% of autopsies on patients > 60 yrs of age reveal a meningioma.[23] Meningiomas account for 39% of primary intracranial neoplasms and 54.5% of non-malignant tumors in the U.S.[2] Incidence peaks at 45 years of age. The median age at diagnosis is 65 years, and the risk increases with age (from an incidence of 1.49/100,000 for ages 20-34 years, to 57.29 for age > 85).[2] Female:male ratio is 2.3:1 in the U.S.[2]

Meningiomas comprise 1.7% of primary brain & CNS tumors in patients age 0-14 years, and 4.6% for ages 15-19 years.[2] 19–24% of adolescent meningiomas occur in patients with neurofibromatosis type I (von Recklinghausen's).

Evaluation

See "Imaging" below for specific findings.

Brain MRI, without and with contrast, is the diagnostic study of choice.

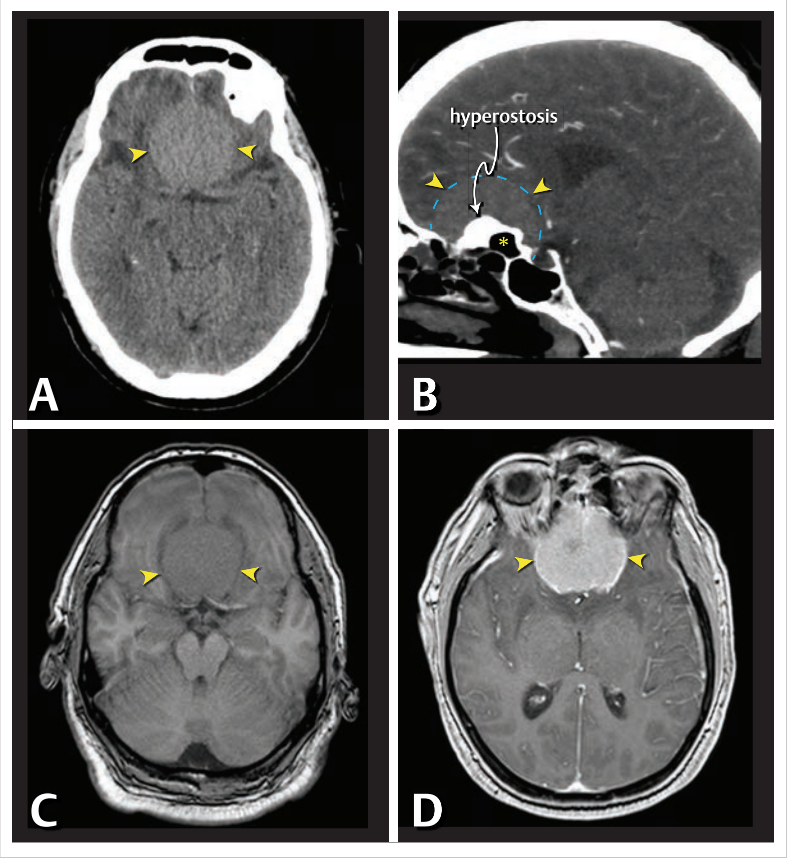

Fig. 46.7 Planum sphenoidal meningioma (*yellow arrowheads*).
Image: A: axial noncontrast CT scan. The tumor is visible although close to brain in density.
B: sagittal CTA. The tumor is barely visible, and has been outlined by a *broken blue line*. Note the hyperostosis of bone at the base of the tumor which is common with meningiomas. There is also enlargement of the underlying air sinus (*yellow asterisk* *), a condition that is termed pneumosinus dilitans.
C: axial noncontrast T1 MRI, and D: axial contrast T1 MRI.

CT without and with contrast scan is second choice when MRI cannot be done, and may also be considered when the identification of calcifications or reactive bone changes is considered crucial, or sometimes for surgical planning.

Angiography may be considered when more definitive assessment of dural sinus occlusion is desired, or to determine if pre-op embolization is a viable intervention.

In questionable cases, a metastatic workup (p. 914) might be considered to rule out that possibility.

Imaging

CT

(See below for characteristic findings shared between CT and MRI). Without contrast, meningiomas are typically homogeneous, isodense or slightly hyperdense to brain on CT (▶ Fig. 46.4 panel A).

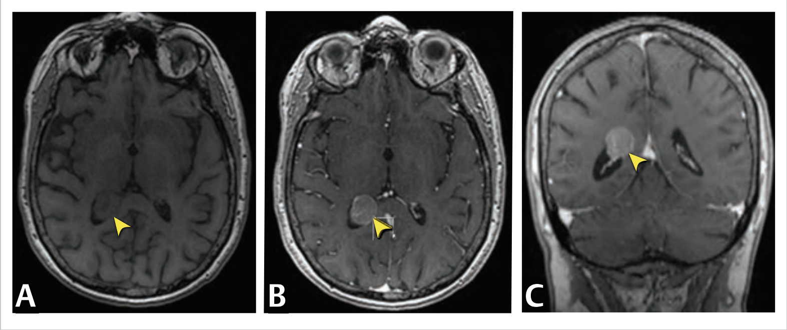

Fig. 46.8 Intraventricular meningioma (*yellow arrowheads*) in the atrium of the right lateral ventricle.
Image: MRI, A: axial T1 without contrast, B: axial T1 with contrast, C: coronal T1 with contrast.
The patient presented with entrapped occipital and temporal horns of the right lateral ventricle.

20-30% have areas of calcification (better appreciated on CT than MRI). Non-contrast Hounsfield numbers of 60–70 in a meningioma usually correlate with presence of psammomatous calcifications (p. 803). On CT, prostate cancer may mimic meningioma (prostate mets to brain are rare, but prostate frequently goes to bone, and may go to skull and can cause hyperostosis).

MRI

(See below for characteristic findings shared between CT and MRI). Meningiomas may be isointense to brain on T1 or T2 images (making them difficult to visualize) but most enhance with gadolinium. Calcifications appear as signal voids on MRI. MRI gives information regarding patency of dural venous sinuses (accuracy in predicting sinus involvement is ≈ 90%[24]).

Characteristic findings on CT or MRI

1. **broad base of attachment** to the meninges
2. **dural tail:** enhancing extension along the dura where the tumor attaches to the meninges (► Fig. 46.4 panel D) (this is not pathognomonic and can also occur with a lower incidence in many conditions such as pleomorphic xanthoastrocytoma (PXA), Rosai-Dorfman disease, plasmacytoma…). The dural tail may be comprised of tumor itself, reactive fibrovascular tissue, and to a limited extent and in only ≈ one third of cases, tumor infiltration of the dura[25]
3. **hyperostosis** (or sometimes blistering) of adjacent bone is very suggestive of meningioma (► Fig. 46.7 panel B). Usually better appreciated on CT than MRI
4. **edema** of the adjacent brainmay be minimal or may be marked especially in certain meningioma subtypes (secretory, angiomatous/microcystic, lymphoplasmacyte-rich, and high-grade meningiomas).[26] Significant edema may be considered to be a criteria for surgical excision (p. 813). Intraventricular meningiomas: 50% produce extraventricular edema
5. **enhancement**: meningiomas usually enhance densely and uniformly, although there may be cystic areas and/or areas of calcification that do not enhance

Angiography

Classic pattern: appears early in arterial phase, blush persists beyond venous phase ("comes early, stays late"). The distinctive prolonged homogeneous tumor blush can also help confirm the diagnosis.

Meningiomas characteristically have *external* carotid artery feeders. Some notable exceptions that feed from the ICA:

1. low frontal median meningiomas (e.g., olfactory groove): feed from ethmoidal branches of the ophthalmic artery
2. suprasellar meningiomas: may also be fed by large branches of the ophthalmic arteries
3. parasellar meningiomas: tend to feed from the ICA. Secondary vascular supply may be derived from pial branches of the anterior, middle, and posterior cerebral arteries
4. petroclival meningiomas: supplied via the artery of the tentorium (a branch of the meningohypophyseal trunk) AKA the **artery of Bernasconi & Cassinari** (the so-called "Italian" artery) which is enlarged in lesions involving tentorium (e.g., tentorial meningiomas)

Angiography also gives information about occlusion of dural venous sinuses, especially for parasagittal/falx meningiomas (may be more accurate than MRI for this). Oblique views are often best for evaluating patency of the superior sagittal sinus (SSS). Angiography also provides an opportunity for pre-op embolization (p. 815) (see below).

Plain X-rays

May show: calcifications within the tumor (in ≈ 10%), hyperostosis or blistering of the skull (including floor of frontal fossa with olfactory groove meningiomas), enlargement of vascular grooves (especially middle meningeal artery). Most of these findings are better appreciated on bone window CT scan.

Differential diagnosis/diagnostic considerations of meningioma

1. pleomorphic xanthoastrocytoma (PXA) (p. 698): may mimic meningiomas since they tend to be peripherally located and may have a dural tail
2. solitary fibrous tumor (▶ Fig. 47.2): (formerly hemangiopericytoma) a rapidly growing tumor
3. gliosarcomas (p. 665), especially ones that are predominantly carcomatous
4. Rosai-Dorfman disease: especially if extracranial lesions are also identified. A connective tissue disorder with sinus histiocytosis and massive painless lymphadenopathy (most have cervical lymphadenopathy). Usually in young adults. Isolated intracranial involvement is rare. MRI: dural-based enhancing mass with signal characteristics similar to meningioma, may have dural tail. Most common intracranial locations: cerebral convexities, parasagittal, suprasellar, cavernous sinus. Pathology: dense fibrocollagenous connective tissue with spindle cells and lymphocytic infiltration, stains for CD68 & S-100. Histiocytic proliferation without malignancy. Foamy histiocytes are characteristic. Surgery and immunosuppressive therapy not effective. Low-dose XRT may be the best option
5. NB: multiple meningiomas suggests the possibility of neurofibromatosis 2 (p. 640) (NF2)

Treatment in general

Indications for treatment

Treatment is indicated for meningiomas with any of the following:

1. symptoms that cannot be satisfactorily controlled medically (e.g., refractory seizures)
2. significant growth on serial imaging studies (see ▶ Table 46.3 for what may constitute “significant growth”)
3. more than minimal edema on imaging

“Significant growth”: the definition is controversial. Proposed criteria includes any of those shown in ▶ Table 46.3

Table 46.3 Various proposed criteria for “significant growth” of meningiomas

• 2-5 mm increase in diameter over 1 year[27]* • 1 cc increase in volume in 1 year[28] • or 15% increase in volume over 1 year[29]
* the concern with using a linear measurement such as diameter is that the volume of a sphere is proportional to the cube of the radius, so for a small tumor a small change in diameter results in a small increase in volume, but for a large tumor the increase in volume with even a small increase in diameter can be substantial

▶ **Asymptomatic meningiomas.** Data is lacking to make evidence-based management guidelines. Incidental meningiomas with no brain edema or those presenting only with seizures that are easily controlled medically may be managed expectantly with serial imaging as meningiomas tend to grow slowly, and some may “burn out” and cease growing.

A suggestion is to obtain a follow-up imaging study 3–4 months after the initial study to rule out rapid progression (often indicating a higher grade meningioma or other lesion), and then if growth is not significant (see ▶ Table 46.3), repeat annually for at least 2–3 years. If stable, follow-up studies could be spaced out further. Treatment would be recommended for significant growth. The development of symptoms should prompt performing a study at the time of the symptoms.

“High-risk meningiomas” (atypical meningiomas, rhabdoid meningiomas, malignant meningiomas, and any meningioma with a high proliferation index) tend to have higher growth rates.

Treatment options

Surgery is the treatment of choice for accessible meningiomas meeting indications for treatment (see above) in patients who are surgical candidates. The perioperative morbidity rate is statistically significantly higher in patients > 70 years old (23%) than in those < 70 (3.5%).[10] See below for details.

Radiation therapy is used most often as adjuvant therapy after surgery for some cases of tumor recurrence or incomplete resection (see post-op radiation (p. 814)). Use as a primary therapy might occasionally be considered for patients who are not surgical candidates or for some deep inaccessible tumors.

MRI-guided **laser interstitial thermal therapy** (LITT): early experience with recurrent meningiomas shows potential, demonstrating early (first few weeks) increase in tumor volume with a subsequent decrease at 3 months and subsequent re-growth in some,[30] requiring further study. This may be a consideration for patients needing treatment when surgery is not a consideration and when maximal XRT has already been given.

Focused ultrasound (FUS) may become a non-invasive adjuvant therapy option for some deep situated tumors. Superficially located meningiomas (especially convexity meningiomas) are generally not candidates for transcranial FUS due to the inability to focus the ultrasound beams near the convexity of the skull.

Radiation therapy (XRT)

► **As primary treatment.** Generally regarded as ineffective as primary modality of treatment. Also, due to long-term risks of XRT, it is usually avoided for "benign" lesions (WHO grade 1) if there are other effective options. Primary XRT may be considered for symptomatic or progressive tumors if the risks of surgical resection (including risks of patients who are poor surgical candidate) outweigh the benefits.

► **Post-op XRT.** Efficacy of XRT in preventing recurrence is controversial—see box for suggestions.

A retrospective series of 135 non-malignant meningiomas followed 5–15 years post-op at UCSF revealed a recurrence rate of 4% with total resection, 60% for partial resection without XRT, and 32% for partial resection with XRT.[31] Mean time to recurrence was longer in the XRT group (125 mos) than in the non-XRT group (66 mos). These results suggest that XRT may be beneficial in partially resected meningiomas. Alternatively, one can follow these patients with CT or MRI and use XRT for documented progression if repeat surgery is not desired.

Atypical meningiomas (WHO grade 2): there are no large prospective studies. Retrospective and/or small studies suggest a nonsignificant trend towards longer PFS with post op XRT, but no difference in OS.

Σ: Post-op XRT suggestions (these are not guidelines)

WHO grade 1 meningiomas: post-op XRT is not recommended even with subtotal resection unless there is progressive growth on follow-up imaging and repeat surgery is not viable (e.g., risky tumor location, poor medical condition…) or desired by patient and surgeon.

Post-op XRT is suggested for **high-risk meningiomas** defined as[32]:

1. anaplastic (WHO grade 3) regardless of extent of resection
2. new atypical meningiomas (WHO grade 2) with *subtotal* resection (Simpson grade ► Table 46.4 IV - V)
3. recurrent atypical meningiomas regardless of extent of resection

New atypical meningiomas (WHO grade 2) with gross total resection (Simpson grade ► Table 46.4 I - III): patient may be followed and then treated with XRT for recurrence.

Dosing for anaplastic or atypical meningioma: fractionated therapy to a dose of 55–60 Gy.

In addition to the usual side effects of XRT—see Radiation injury and necrosis (p. 1899)—there is a risk of radiation-induced tumors such as astrocytomas.[33]

Surgical treatment for meningiomas

General information

Surgical goals: complete resection when possible, with removal of involved meninges and bone when feasible. The Simpson grading system for extent of meningioma resection is shown in ► Table 46.4.

Table 46.4 Simpson grading system for removal of meningiomas[50]

Grade	Degree of removal	Recurrence rate (%)
I	macroscopically complete removal with excision of dural attachment and abnormal bone (including sinus resection when involved)	9
II	macroscopically complete with endothermy coagulation (electrocautery or laser) of dural attachment	19
III	macroscopically complete without resection or coagulation of dural attachment or of its extradural extensions (e.g., hyperostotic bone)	29
IV	partial removal leaving tumor in situ	44
V	simple decompression (± biopsy)	N/A

Meningiomas are often very bloody. Preoperative embolization may be helpful for specific tumors (see below). Pre-op autologous blood donation may also be a consideration.

General principles of meningioma surgery[34]:

1. early interruption of the arterial blood supply to the tumor: unfortunately, the blood supply is often on the deep aspect of the tumor and may be difficult to access early in the resection
2. to avoid excessive retraction on the brain, a common technique consists of
   a) internal decompression (debulking) of the tumor using ultrasonic aspirator, cautery loops…
   b) followed by collapsing the tumor capsule into the area of decompression and dissectiing the capsule from the brain by cutting and coagulating vascular and arachnoid attachments
3. removal of attached bone and dura when possible

Pre-op tumor embolization: Reduces the vascularity of these often bloody tumors, facilitating surgical removal. Timing of subsequent surgery is controversial. Some advocate waiting 7–10 days to permit tumor necrosis, which simplifies resection.[35,36] Complications include: hemorrhage (intratumoral and SAH), cranial nerve deficits (usually transient), stroke from embolization through ICA or VA anastomoses, scalp necrosis, retinal embolus, and potentially dangerous tumor swelling. Many meningiomas are not readily amenable to embolization (e.g., olfactory groove meningioma).

Position

As usual, the head should be elevated ≈ 30° above the right atrium.

For meningiomas involving the superior sagittal sinus (SSS)[37]:

- for tumors involving the anterior third of the SSS: supine semi-sitting position
- for tumors of the middle third of the SSS: lateral position with the side of the tumor *down*, the neck tilted 45° toward the upward shoulder
- for tumors of the posterior third of the SSS: prone position

Sinus involvement

Greenberg IMHO

Due to unappreciated venous drainage (see text), attempting to occlude or bypass the middle third of the superior sagittal sinus involved with meningioma is treacherous. Even in expert hands, there is significant risk of venous infarction/sinus occlusion with 8% morbidity and 3% mortality,[16] and complete removal is still not assured.[38] Rather than risking venous infarctions, it is almost always preferable to leave residual tumor and follow with serial imaging (especially for WHO grade 1 meningiomas, and with some grade 2 lesions (p. 814)) and consider treating with repeat surgery or radiation therapy as appropriate.

Alternatives for treatment of dural sinus involvement include:

► **Superior sagittal sinus (SSS). If the tumor occludes the SSS**, it has been suggested that the sinus can be resected carefully, preserving veins draining into the patent portions of the sinus. ✖ However, this should be undertaken under advisement since patients still not infrequently develop venous infarcts, probably as a result of loss of venous drainage of even minimal sinus flow, venous channels in the dura adjacent to the sinus, through the skin or bone of the skull, and even the tumor itself may participate. Before ligating the sinus, the lumen should be inspected for a tail of tumor within the sinus.

Partial occlusion of superior sagittal sinus:

1. anterior to the coronal suture, the sinus may usually be divided safely
2. posterior to the coronal suture (or, perhaps more accurately, posterior to the vein of Trolard), it must not be divided or else severe venous infarction will occur
   a) with superficial involvement (Type I, ▶ Fig. 46.5), tumor may be dissected off the sinus with care to preserve patency
   b) with extensive involvement:
      - sinus reconstruction: hazardous. Thrombosis rate using venous graft approaches 50%, and is close to 100% with artificial grafts (e.g., Gore-Tex) which should *not* be used
      - it may be best to leave residual tumor, and follow with CT or MRI. If the residual tumor grows, or if the Ki-67 score is high (p. 805), SRS may be used; SRS (p. 1903) may also be used as initial treatment for tumors that are < 2.3–3 cm diameter

▶ **Transverse sinus (TS).** A patent dominant TS must not be suddenly occluded.

Convexity meningiomas

NB: the tumor capsule of convexity meningiomas that straddle the Sylvian fissure may be adherent to branched of the middle meningeal artery and must be carefully dissected off of the tumor to avoid damage to them.

The craniotomy should be large enough (ideally 1-2 cm beyond the tumor attachment) to permit excising the invaded dura adjacent to the point of tumor attachment. Dura directly involved with the tumor must be resected, and an autograft (e.g., fascia lata or periosetum from an uninvolved location) or allograft will be required.

▶ **Dural tail.** The dural tail is infrequently comprised of dura invaded by tumor (p. 812), and it is not always necessary to remove it all. Current practice is generally to excise as much of the dural tail as is reasonably possible without chasing it for long distances.

▶ **Bone involvement. Hyperostosis** of bone adjacent to a meningioma: occurs in 5-44%.[39] Various pathologic mechanisms have been invoked,[40] and only in some cases is frank tumor invasion present. MRI often shows increased T2 signal extending beyond the limits of hyperostosis. The hyperostotic bone can usually be drilled off the surface of the bone flap which may then be replaced.

Bone invasion: if extensive, the bone flap may have to be discarded and replaced with a cranioplasty (at the time of surgery, e.g., using titanium mesh, or at a later date). Alternatively, the invaded bone may be excised from the center of the flap and the resultant defect is often significantly smaller than the flap and is more easily patched, and the patched flap can then be reimplanted.

A study in which bone biopsies were taken 2 cm outside the hyperostotic margin were negative for tumor in all 12 cases of grade 1 & 2 meningiomas (even where there was increased signal on T2 MRI), whereas in the 2 cases of grade 3 meningioma all biopsies were positive.[41]

Sphenoid wing, parasagittal, or falx meningiomas (general principles)

Once tumor is exposed a partial internal debulking is performed. Then the point of attachment (to the falx or sphenoid bone) is peeled away using bipolar cautery to divide feeding vessels. Then the main portion of the tumor may be separated from the brain, with the tumor being avascular once the vascular pedicle has been transected.

Parasagittal and falx meningiomas

The inferior portion of the tumor may adhere to branches of the anterior cerebral artery. Middle or posterior third tumors are exposed using a horseshoe incision based in the direction of the major scalp feeding vessels. Alternatively, the patient may be placed in a lateral position, or the sitting position may be used with Doppler monitoring for air embolism (p. 1738). Anterior third tumors are approached using a bicoronal skin incision with the patient supine. For tumors that cross the midline, burr holes are placed to straddle the SSS. For managing superior sagittal sinus involvement, see above.

Since these tumors are often debulked from the inside, removal tends to be bloodier than meningiomas that can be removed in 1 piece. The ability to embolize these tumors pre-op is somewhat limited, but may be an adjunct. For tumors involving the convexity dura, cut through tumor leaving a thin layer on dura. Then remove the now relatively avascular part that impresses the brain. Then make an incision through the dura near the tumor; it tends to be bloody, but once you have control of both sides of the dura you can begin to excise the dura around the tumor (you may need to leave a cuff on SSS if it is involved).

Sphenoid wing meningiomas

A pterional craniotomy (p. 1748) is utilized. The neck is extended to allow gravity to retract the brain off of the floor of the skull.

Lateral sphenoid wing meningiomas: The approach to these tumors is often similar to convexity meningiomas. The height of the skin incision and bone opening should be high enough to encompass the tumor.

Medial sphenoid wing meningiomas: A lumbar drain is used. The head is turned 30° off the vertical. Aggressive extradural removal of sphenoid wing is performed. An FTOZ approach may provide additional exposure. The Sylvian fissure is split widely. The ICA and MCA are often encased by tumor (look for the appearance of "grooves" on the surface of the tumor on MRI, which indicates vessels, e.g., MCA). To locate the ICA, identify MCA branches and follow them proximally into the tumor. The optic nerve is best identified at the optic canal. Avoid excessive retraction of the optic apparatus. The deep portion of the tumor often has numerous small parasitic vessels from the ICA (which makes this part very bloody), and may also invade the lateral wall of the cavernous sinus (which creates risk of cranial nerve deficits with attempted removal). Therefore, the recommendation is to leave some tumor behind and use radiosurgery to deal with it.

Olfactory groove meningiomas

Approached via a bifrontal craniotomy (preserving the periosteum to cover the frontal air sinus and floor of frontal fossa at the end of the case). Small tumors may be approached via unilateral craniotomy on the side with the most tumor.[42(p 3284)] For large tumors, a lumbar CSF drain will help with brain relaxation[13] and the head is rotated 20° to one side to facilitate dissection of the anterior cerebral arteries and optic nerve while preserving visualization of both sides of the tumor involvement.[43] The neck is slightly extended. The dura is opened low, and the superior sagittal sinus is ligated and divided at this location. Amputation of the frontal pole should be done if necessary to avoid excessive retraction. Vascular feeding arteries come through the floor of the frontal fossa in the midline. Initially, the anterior tumor capsule is opened and the tumor debulked from within, heading towards the floor of the frontal fossa to interrupt the blood supply. The posterior capsule of the tumor is dissected carefully as this portion of the tumor may encase branches of the anterior cerebral artery, and/or optic nerves and chiasm. A large tumor with suprasellar extension usually displaces the optic nerve and chiasm *inferiorly*.[13] If necessary, the frontopolar branch and other small branches may be sacrificed without problem.[44] Periosteum is laid over the floor of the frontal fossa. To hold it in place, one may attempt to suture it to the adjacent dura with a couple of retaining sutures, alternatively a small titanium plate (e.g., "dogbone") can be placed over the flap and screws are placed into the bone of the floor of the frontal fossa (both methods are challenging). Post-op risks include CSF leak through the ethmoid sinuses.

Tuberculum sellae meningiomas

These tumors typically displace both optic nerves posteriorly and laterally.[13] Occasionally, the nerves are completely engulfed by tumor.

Cerebellopontine angle meningiomas

Usually arise from the meninges covering the petrous bone. May be divided into those that occur anterior to, and those that occur posterior to the IAC.

Foramen magnum meningiomas

Tumors arising from the posterior or posterolateral lip of the foramen magnum (FM) are removed relatively easily. Anterior and lateral FM tumors may be operated by the posterolateral approach, and for anterior tumors,[18] a transcondylar approach may alternatively be used.[45]

With meningiomas below the vertebral artery (VA), the lower cranial nerves are displaced superiorly with the VA. However, when the tumor is above the VA, the position of the lower cranial nerves cannot be predicted.[18]

Large tumors may adhere to or encase neurovascular structures, and these should be internally debulked and then dissected free.

Posterior suboccipital approach: Used for meningiomas arising from the posterior lip of the FM or slightly posterolateral.

The patient is positioned prone or three-quarter prone. Neck flexion should be kept to a minimum to avoid brainstem compression by the tumor.[46] The surgeon must remain vigilant for the PICA and vertebral arteries, which may be encased.

Recurrence after surgery

The most powerful *histopathologic* predictor of recurrence is WHO grade, with grade 1 recurrence rate of 7-25%, grade 2 recur in 29-52%, and grade 3 in 50-94%. Some histologic subtypes are also more prone to recurrence (as noted under subtypes).

The extent of surgical tumor removal is the most important factor in the prevention of post-op recurrence. The Simpson grading system for the extent of meningioma removal is shown in ▶ Table 46.4. An often overlooked aspect of the Simpson grading system is that it refers exclusively to the removal of *intradural* tumor, and thus leaving the tumor e.g., in the sagittal sinus could still be considered "complete removal." Recurrence after gross total tumor removal occurred in 11–15% of cases, but was 29% when removal was incomplete (length of follow-up not specified)[11]; 5-year recurrence rates of 37%[47]-85%[48] after partial resection are also quoted. The overall recurrence rate at 20 years was 19% in one series,[49] and 50% in another.[48] Malignant meningiomas have a higher recurrence rate than benign ones.

Prognosis

5-year survival for patients with meningioma[51]: 91.3%. With anaplastic meningiomas, median survival ranges from < 2 years to > 5 years depending on completeness of removal and use of adjuvant XRT.[6]

47 Mesenchymal, Non-meningothelial Tumors

47.1 General information

Benign and malignant mesenchymal tumors originating in the CNS are very rare and are organized using terminology and histologic features corresponding to their soft tissue and bone counterparts as outlined in the 2020 WHO Classification of Soft Tissue & Bone Tumors, 5th edition.[1]

Primary mesenchymal tumors relating to the brain and spine tend to arise in the meninges rather than in the parenchyma, and occur more often in the supratentorial compartment than in the p-fossa or spine.

47.2 Fibroblastic and myofibroblastic tumors

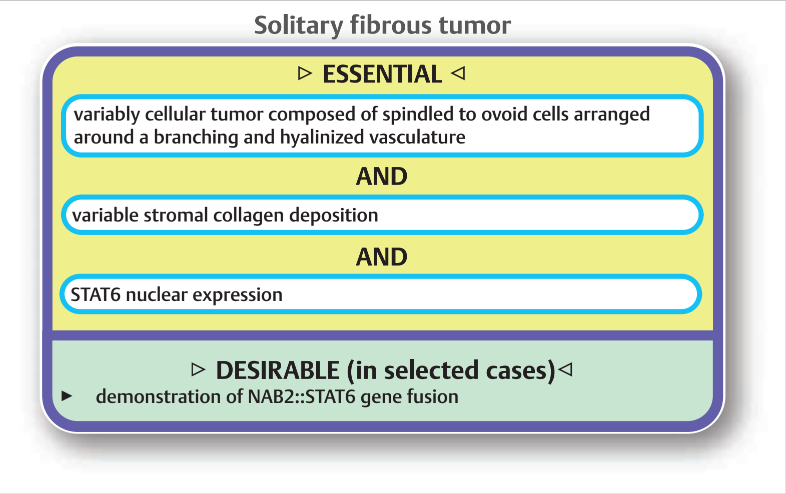
47.2.1 Solitary fibrous tumor (WHO grade 1, 2 or 3)

General information

A mesenchymal tumor of the fibroblastic type with genomic inversion at the 12q13 locus in most solitary lesions, producing *NAB2* and *STAT6* gene fusion and STAT6 nuclear expression, with a high chance of recurrence and metastases. Formerly included hemangiopericytomas—an obsolete term. Cells are spindle to ovoid, located amidst dilated thin-walled blood vessels. Calcifications including psammoma bodies have not been observed. There is a case report of a tumor releasing IGF-2 causing hypoglycemia.[2]

Diagnostic criteria for solitary fibrous tumor

Diagnostic criteria for solitary fibrous tumor are shown in ▶ Fig. 47.1.[3]



Solitary fibrous tumor

▷ ESSENTIAL ◁

variably cellular tumor composed of spindled to ovoid cells arranged around a branching and hyalinized vasculature

AND

variable stromal collagen deposition

AND

STAT6 nuclear expression

▷ DESIRABLE (in selected cases)◁

▶ demonstration of NAB2::STAT6 gene fusion

Fig. 47.1 Diagnostic criteria for solitary fibrous tumor. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Grading

The degree of mitotic activity and the presence of necrosis correlates with prognosis:

- WHO grade 1 (ICD-O 8815/0): hypocellular, collagenized tumor with a classic solitary fibrous tumor phenotype. < 2.5 mitoses/mm^2 (< 5 mitoses/10 high powered fields)

- WHO grade 2 (ICD-O 8815/1): more dense. ≥ 2.5 mitoses/mm^2 (≥ 5 mitoses/10 HPF)
- WHO grade 3 (ICD-O 8815/3): ≥ 2.5 mitoses/mm^2 (≥ 5 mitoses/10 HPF) with tumoral necrosis

Imaging

Radiographically may be mistaken for a meningioma (▶ Fig. 47.2).

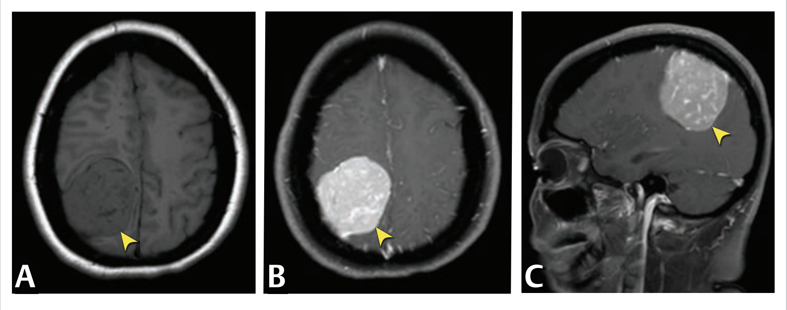


Fig. 47.2 Solitary fibrous tumor (*yellow arrowheads*), right parietal.
Image: MRI, A: T1 without contrast and B: with contrast; C: sagittal T1 with contrast. Note features that may be mistaken for meningioma: broad base of attachment, iso-intense with brain on T1 & T2 noncontrast sequences, dense enhancement with contrast.

Treatment

Surgery is the primary treatment. Grades 2 & 3 benefit from adjuvant XRT. Chemotherapy is used for metastases or for tumors failing local control measures.

Prognosis

SFTs tumors have a high rate of recurring and/or metastasizing, as late as decades after initial diagnosis. Therefore, long-term follow-up is advised. Unlike SFTs outside the CNS, advanced age does not correlate with worse outcome.

47.3 Vascular tumors

47.3.1 Hemangioma (WHO grade 1)

General information

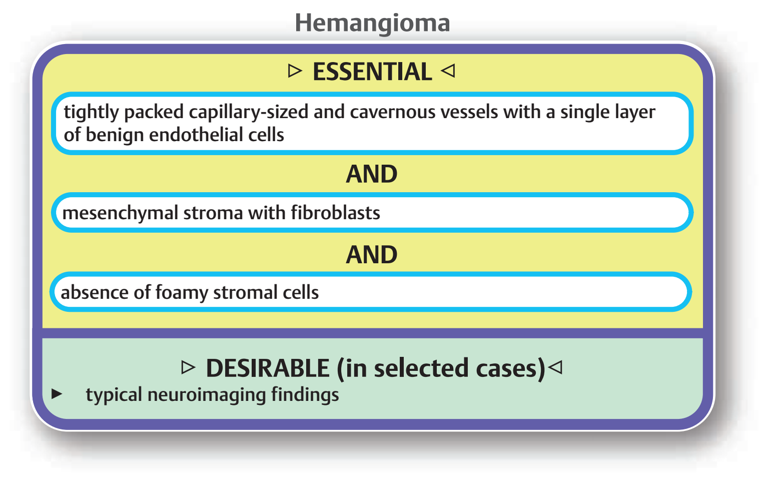
Hemangiomas are benign neoplastic lesions with multiple closely approximated vessels lined by a single cell layer of bland endothelial cells with very rare mitoses. The vessels range in size from capillary-sized vessels (so-called **capillary hemangioma,** ICD-O 9131/0) to dilated vessels with flattened endothelial lining (so-called **cavernous hemangioma,** ICD-O 9131/0). They form lobules that are each supplied by a separate artery and separated by a fibrous septation. Hemangiomas may be solitary, multiple, or part of a *PIK3CA*-related overgrowth syndrome. Refer to details on vertebral hemangiomas (p. 992).

Diagnostic criteria for hemangioma

Diagnostic criteria for hemangioma are shown in ▶ Fig. 47.3.[3]

Location

Hemangiomas originate most frequently in the spine (p. 992), followed by the skull (p. 973), and uncommonly in the brain parenchyma, nerve roots and cauda equina. In the spine, there is a predilection for the thoracic and lumbar regions, and they are often multiple (p. 992).



Hemangioma

▷ ESSENTIAL ◁

tightly packed capillary-sized and cavernous vessels with a single layer of benign endothelial cells

AND

mesenchymal stroma with fibroblasts

AND

absence of foamy stromal cells

▷ DESIRABLE (in selected cases)◁

▶ typical neuroimaging findings

Fig. 47.3 Diagnostic criteria for hemangioma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Imaging

In the spine, suggestive findings include polka-dot sign on axial images, or corduroy pattern on longitudinal images (p. 992). Calcifications are frequent, and are well demonstrated on CT.

T2-MRI shows mixed signal internally. The surrounding hemosiderin ring is low density on T2 with blooming artifact.

47.3.2 Hemangioblastoma (WHO grade 1)

General information

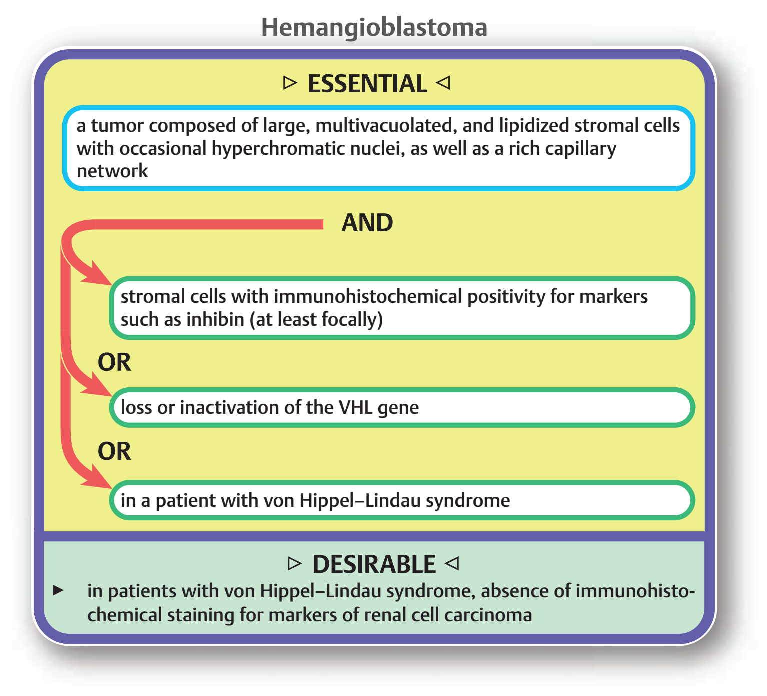
Key concepts

- highly vascular well-circumscribed benign solid or cystic neoplasm of CNS or retina
- the most common *primary intra-axial* tumor in the adult posterior fossa
- may occur sporadically (70%) or as part of von Hippel-Lindau disease (30%), and any patient with HGB should be screened for VHL
- on imaging, may be solid, or cystic with enhancing mural nodule (for cysts with mural nodule, surgically, the cyst wall does not need to be removed)
- ✓ CBC: may be associated with erythrocytosis (polycythemia)

Hemangioblastomas (HGB) are extremely vascular histologically benign slow growing tumors comprised of neoplastic stromal cells with clear to vacuolated cytoplasm and copious small vessels with characteristic immunohistochemical features (e.g., staining for inhibin) and molecular signatures (e.g., *VHL* laterations). They may occur sporadically or as part of von Hippel-Lindau disease (p. 646). HGBs are difficult to distinguish histologically from a renal cell carcinoma (which is common in VHL and adds to the difficulty of this differential).

Diagnostic criteria for hemangioblastoma (HGB)

Diagnostic criteria for hemangioblastoma are shown in ▶ Fig. 47.4.[3]



Hemangioblastoma
▷ ESSENTIAL ◁
a tumor composed of large, multivacuolated, and lipidized stromal cells with occasional hyperchromatic nuclei, as well as a rich capillary network
AND
stromal cells with immunohistochemical positivity for markers such as inhibin (at least focally)
OR
loss or inactivation of the VHL gene
OR
in a patient with von Hippel–Lindau syndrome
▷ DESIRABLE ◁
► in patients with von Hippel–Lindau syndrome, absence of immunohistochemical staining for markers of renal cell carcinoma

Fig. 47.4 Diagnostic criteria for hemangioblastoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Location

Intracranially, they occur almost exclusively in the p-fossa (hemangioblastomas are the most common *primary* intra-axial p-fossa tumor in adults). May occur in the cerebellar hemisphere, vermis, or brainstem. May also occur in the spinal cord (p. 986) (1.5–2.5% of spinal cord tumors). Retinal HGB and/or angiomas occur in 6% of patients with cerebellar HGBs.

Epidemiology

HGB represent 1–2.5% of intracranial tumors. They comprise 7–12% of primary p-fossa tumors.[4]

70% of HGBs occur sporadically, but 30% occur as part of von Hippel-Lindau (VHL) disease (p. 646).[5] 5–30% of cases of cerebellar HGB and 80% of spinal HGB are associated with VHL.

Sporadic cases tend to present in the 4th decade, whereas VHL cases present *earlier* (peak in 3rd decade). In sporadic cases, the HGB are solitary and originate in the cerebellum (83–95%), spinal cord (3–13%), medulla oblongata (2%)[6] or cerebrum (1.5%).[4] In 65% of patients with VHL the HGB are multiple.

Presentation

S/S of cerebellar HGB are usually those of any p-fossa mass—H/A, N/V, cerebellar findings…; see Posterior fossa (infratentorial) tumors (p. 624)—and obstructive hydrocephalus may occur. HGB is rarely documented as a cause of apoplexy due to intracerebral hemorrhage (ICH) (lobar or cerebellar); however, some studies indicate that if cases of ICH are carefully examined, abnormal vessels consistent with HGB (and occasionally misidentified as AVM) may be found with surprising frequency (in spite of negative CT and/or angiography).[7]

Retinal HGBs tend to be located peripherally, and may hemorrhage and cause retinal detachment.

Erythrocytosis may be due to erythropoietin liberated by the tumor.

Histology

Invasion of adjacent neural tissue is rare. Mitotic figures are rare. No true capsule, but usually well circumscribed (narrow zone of infiltration). May be solid, or cystic with a mural nodule (70% of cerebellar lesions are cystic; nodules are very vascular, appear red, are often located near pial surface, and may be as small as 2 mm; cyst fluid is clear yellow with high protein). In cystic lesions, the cyst wall is lined with non-neoplastic compressed cerebellum. The cyst develops because the vessel walls are so thin that they leak water, and proteins don't cross as readily.

Cardinal feature: numerous capillary channels, lined by a single layer of endothelium, surrounded by reticulin fibers (stains positive with reticulin stain). Macrophages stain PAS positive.

Two main component cells:

1. stromal cells: polygonal. Characteristic and distinguishing finding: plentiful lipid laden vacuoles,
2. reactive vascular cells

Cyst patterns[8]:

1. no associated cysts: 28%
2. peritumoral cyst alone: 51%
3. intratumoral cyst: 17%
4. peritumoral AND intratumoral cysts: 4%

Evaluation

Patients with a p-fossa HGB (radiologically suspected or histologically proven) should undergo MRI of entire neuraxis because of possibility of spinal HGBs (may be distant from p-fossa lesion; may suggest possibility of VHL).

CT: solid lesions are usually isodense with intense contrast enhancement. Cystic HGBs remain low density with contrast, with the nodule enhancing.

MRI (▶ Fig. 47.5): preferable to CT due to the predilection of HGBs for the p-fossa. May show serpentine vascular signal voids, especially in the periphery of the lesion. Also, peripheral hemosiderin deposits may occur from previous hemorrhages.[4]

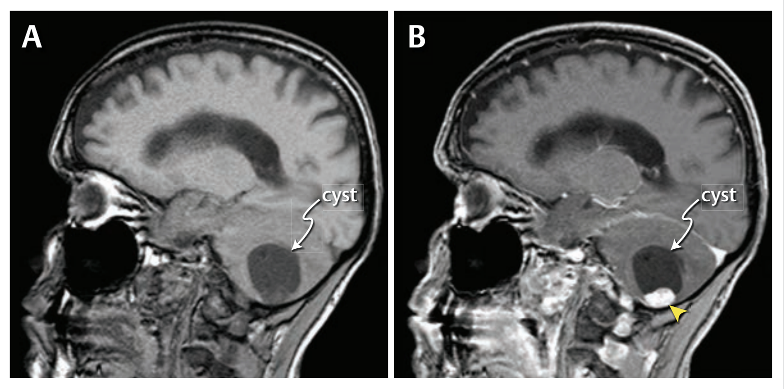


Fig. 47.5 Hemangioblastoma of the posterior fossa. Demonstrates cyst with enhancing mural nodule (*yellow arrowhead*). Image: Sagittal MRI, A: T1 noncontrast, B: T1 + contrast.

Vertebral angiography: usually demonstrates intense vascularity (most other tumors of the p-fossa are relatively avascular). May be required in HGBs where nodule is too small to be imaged on CT/MRI. 4 patterns: 1) vascular mural nodule on side of avascular cyst, 2) vascular lesion surrounding avascular cyst, 3) solid vascular mass, and 4) multiple, separate vascular nodules.

Labs: often discloses *polycythemia* (no hematopoietic foci within tumor). In cases with suggestive history, labwork to rule out catecholamine production from pheochromocytoma may be indicated; see Endocrine/laboratory studies (p. 942).

Treatment

Surgery

Surgical treatment may be curative in cases of sporadic HGB, not in VHL. GTR is considered the optimal treatment.[9]

Preoperative embolization may help reduce the vascularity.

Cystic HGBs require removal of mural nodule (otherwise, cyst will recur). The cyst wall is not removed unless there is evidence of tumor within the cyst wall on MRI (typically thick-walled cysts) or visually at the time of surgery.[8] 5-ALA fluorescence may aid in visual localization of small hemangioblastomas within the cyst wall.[10]

Solid HGBs tend to be more difficult to remove. They are treated like AVMs (avoid piecemeal removal), working along margin and devascularizing blood supply. A helpful technique is to shrink the tumor by laying a length of bipolar forceps along tumor surface and coagulating. HGBs with attachment to floor of 4th ventricle may be hazardous to remove (cardio-respiratory complications).

Multiple lesions: if ≥ 0.8–1 cm diameter: may treat as in solitary lesion. Smaller and deeper lesions may be difficult to locate at time of surgery.

Cystic brainstem HGB: the solid nodule of the tumor is removed under the microscope by bipolaring and cutting the gliotic adhesions to the parenchyma. ★ Removal of the cyst wall is not necessary. There is often a cleavage between the tumor and the floor of the fourth ventricle which facilitates tumor removal. To reduce bleeding, avoid piecemeal removal. Preserve large draining veins until the arterial feeders to the mural nodule have been isolated and resected.[11]

Radiation treatment

Effectiveness is dubious. May be useful to reduce tumor size or to retard growth, e.g., in patients who are not surgical candidates, for multiple small deep lesions, or for inoperable brainstem HGB. Does not prevent regrowth following subtotal excision.

Prognosis

Prognosis is excellent following GTR, and is better for sporadic HGB vs. those associated with VHL. No report of malignant change. May spread thru CSF after surgery, but remain benign.

Prognostic factors for *longer* OS in older patients (but not in younger patients) include: GTR vs. STR or biopsy (HR 0.62).

Prognostic factors for *shorter* OS include: age ≥ 40 years (HR 3.9), size, growth pattern, multifocality and brainstem location (vs. cerebellum) (HR 1.9).[9]

47.4 Notochordal tumors

47.4.1 Chordoma

General information

Key concepts

- primary malignant tumor, usually of clivus or sacrum, with high recurrence rate
- histology: characteristic physaliphorous cells (containing intracellular mucin)
- generally slow-growing and radioresistant
- treatment of choice: wide en bloc resection when possible (piecemeal removal carries risk of inducing metastases), proton-beam radiation may help

Rare tumors (incidence of ≈ 0.51 cases/million) of the remnant of the primitive notochord (which normally differentiates into the nucleus pulposus of the intervertebral discs). They represent less than 1% of intracranial tumors and 3% of primary spine tumors.[12]

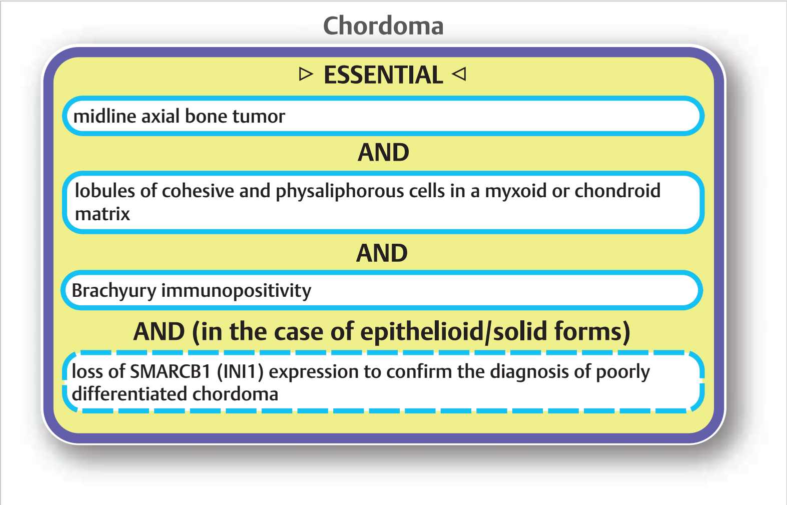
They are slow growing, locally aggressive and osseodestructive.

Histologically, these tumors are considered low-grade malignancies. However, their behavior is more malignant because of the difficulty of total removal, a high recurrence rate (85% following surgery), and the fact that they metastasize (usually late) in 5–20%,[13] (often after multiple resections) typically to lung, liver, and bone. Therefore aggressive XRT is usually employed post-op. Malignant transformation into fibrosarcoma or malignant fibrous histiocytoma is rare. Four types have been identified:

1. conventional: median age: 55 years
2. chondroid: extracellular matrix resembles hyaline cartilage. Median age: 45 years
3. dedifferentiated: biphasic tumors comprised of conventional chordoma adjacent to high grade sarcoma. Nuclear and cytokeratin expression are retained in the conventional chordoma areas, but not in the sarcomatous component. Median age: 61 years
4. poorly differentiated: no physaliphorous cells. Median age: 7 years

Diagnostic criteria for chordoma

Diagnostic criteria for chordoma are shown in ▶ Fig. 47.6.[3]



Chordoma

▷ ESSENTIAL ◁

midline axial bone tumor

AND

lobules of cohesive and physaliphorous cells in a myxoid or chondroid matrix

AND

Brachyury immunopositivity

AND (in the case of epithelioid/solid forms)

loss of SMARCB1 (INI1) expression to confirm the diagnosis of poorly differentiated chordoma

Fig. 47.6 Diagnostic criteria for chordoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Location

Chordomas can arise anywhere along the neuraxis where there is remnant of notochord; however, cases tend to cluster at the two ends of the primitive notochord: 35% cranially[14] in the spheno-occipital region (clivus), and 53%[14] in the spine at the sacrococcygeal region.[15] Less commonly, they may occur in the spine above the sacrum.[16]

Pathogenesis

The notochord is a flexible cartilage-like embryologic structure that requires the protein brachyury (coded for by the *TBXT* gene) to develop. In most individuals, the notochord regresses in utero and by birth has devolved into the nucleus pulposus (the center of spinal intervertebral discs). In a small number of people, remnants of the notochord persist, usually in the odontoid process or coccyx. The process of neoplastic transformation of these remnants is incompletely understood, but mutations have been identified including duplications of the *TBXT* gene in 27%.[17]

Histology

Physaliphorous cells are distinctive, vacuolated cells on histology that probably represent cytoplasmic mucus vacuoles seen ultrastructurally.

Radiographic appearance

Usually lytic, lobular midline lesions with frequent calcifications.[18]

MRI: hypointense on T1WI, hyperintense on T2WI.

Enhances on CT or MRI with contrast.[18] Rarely, they may appear as a sclerotic vertebra[19] ("ivory vertebra").

Cranial chordomas

Peak incidence of cranial chordomas is 50–60 years of age. These tumors are rare in patients < 30 years of age.[20] Male:female distribution is ≈ equal.

Differential diagnosis: Primarily between other cartilaginous tumors of the skull base; see differential diagnosis of other foramen magnum region tumors (p. 1649):

1. chondrosarcomas
2. chondromas

Presentation: Usually produces cranial nerve palsies (usually oculomotor or abducens nerve).

Spinal chordomas

General information

Occur primarily in the sacrococcygeal region. Unlike cranial chordomas, sacrococcygeal chordomas show a male predominance,[14] and these patients tend to be older. May also arise in C2. Chordomas constitute over 50% of primary bone tumors of the sacrum. May produce pain, sphincter disturbance, or nerve root symptoms from local nerve root compression. They may occasionally extend cephalad into the lumbar spinal canal. They are usually confined anteriorly by the presacral fascia, and only rarely invades the wall of the rectum.[21] A firm fixed mass may be palpable between the rectum and the sacrum on a rectal exam.

Evaluation

Characteristic radiographic findings: centrally located destruction of several sacral segments, with an anterior soft-tissue mass that occasionally has small calcifications. CT and MRI show the bony destruction. This is usually difficult to see on plain X-rays. MRI also shows the soft-tissue mass.

Open or CT guided percutaneous *posterior* biopsy can confirm the diagnosis. Transrectal biopsy should be avoided because of the potential of rectal spread of tumor.[22]

Chest CT and bone scan: to R/O mets for staging purposes.

Treatment of spinal chordomas

Surgery

Wide en bloc excision with postoperative radiation is usually the best option, although this may also be only temporarily effective. Decompression is best avoided since entering the mass serves to spread tumor (surgically induced metastases) which will then regrow. Chordomas located in C2 are usually not amenable to en bloc resection.[23]

Sacral chordomas: The particulars of the surgical procedure are highly dependent on the extent of the lesion. These tumors may spread through the gluteal musculature, and if significant muscular excision is required, then a pedicle-based rectus abdominis flap may be employed. A diverting colostomy may be required if it is necessary to resect the rectum or if a cephalic sacral resection is anticipated.[24]

For chordomas caudal to the third sacral segment, most agree that a posterior approach is satisfactory. For more rostral lesions, some advocate a combined anterior-posterior approach. However, a posterior approach has also been used for these.[24]

Adverse effects of sacrectomy: if S2 nerve roots are the most caudal nerve roots spared, there is ≈ 50% chance of normal bladder and bowel control.[24] If S1 or more cephalic roots are the most caudad nerve roots spared, most will have impaired bladder control and bowel problems.[24]

Radiation therapy (XRT)

Best results were obtained with en bloc excision (even if marginal), sometimes combined with high-dose XRT[16,25] (conventional XRT did not prevent recurrence when incorporated with palliative or debulking surgery,[16] but it did lengthen the interval to recurrence[25]). Early radiation was associated with longer survival.[26] Higher XRT doses can be used in the sacrococcygeal region (4500–8000 rads) than in the cervical spine (4500–5500 rads) because of concerns of radiation injury to the spinal cord. IMRT and stereotactic radiosurgery have also been used.[23]

Proton beam therapy, alone[13] or combined with high-energy X-ray (photon) therapy,[27,28] may be more effective than conventional XRT alone. However, proton beam therapy requires travel to one of a limited number of facilities with a cyclotron which may be difficult to arrange for what is typically ≈ 7 weeks of fractionated treatments.

Chemotherapy

Imatinib (Gleevec®) (a tyrosine kinase inhibitor) has some antitumor effect in chordoma.[29]

Prognosis

The prognosis is worse for dedifferentiated and poorly differentiated with median PFS of 6 months and 4 months respectively, and median OS of 15 months and 13 months. Conventional chordomas have a median PFS of 24 months, and median OS of 48 months.[3]

Median survival is 6.3 years.[23]

48 Melanocytic Tumors and CNS Germ Cell Tumors

48.1 Melanocytic tumors

48.1.1 General information

Rare. Diffuse or localized CNS tumors that presumably originate from leptomeningeal melanocytes. Terminology:

1. **circumscribed** melanocytic tumors: rare
   a) meningeal melanocytoma: may be well differentiated. When increased mitotic activity or parenchymal invasion occurs, these qualify as intermediate grade tumors
   b) meningeal melanoma: the malignant counterpart to the above
2. **diffuse** melanocytic tumors are defined by involvement of large areas of the subarachnoid space, with or without focal nodularity
   a) meningeal melanocytosis: benign histology
   b) meningeal melanomatosis: malignant histology. Aggressive and resistant to XRT

These primary CNS lesions may be distinguished from other pigmented CNS neoplasms (e.g., malignant melanotic nerve sheath tumors) using molecular analysis (▶ Table 35.7) and methylation profiling.

48.1.2 Diffuse meningeal melanocytic neoplasms

General information

Rare, primary CNS neoplasms that involve the leptomeninges and spread diffusely throughout the subarachnoid space, sometimes with focal or multifocal nodularity, and frequentl invasion of the Virchow-Robin (perivascular) spaces. There is a predilection for the temporal lobes, cerebellum, pons, medulla, and spinal cord.

Distinguishing these primary tumors from metastases originating outside the CNS is critical for treatment decsions and prognostication, and often requires molecular testing in addition to microscopic histology.

These tumors frequently occur in the setting of neurocutaneous melanosis (p. 653) (a rare neurocutaneous disorder).

Symptoms may be due to hydrocephalus or from dysfunction of invaded brain. Other associations include arachnoid cysts, syringomyelia, other brain tumors (e.g., astrocytoma, ependymoma…), and other structural conditions (e.g., Chiari malformation). Symptoms progress rapidly when malignant transformation occurs.

MRI findings vary with the amount of melanin content, and these tumors may be isodense or hyperintense on T1WI, and hypodense on T2WI.[1]

There are case reports of tumor spreading to the peritoneal compartment when ventriculo-peritoneal shunting is used to treat hydrocephalus.[2]

Diagnostic criteria for diffuse meningeal melanocytic neoplasms

Diagnostic criteria for diffuse meningeal melanocytic neoplasms are shown in ▶ Fig. 48.1.[3]

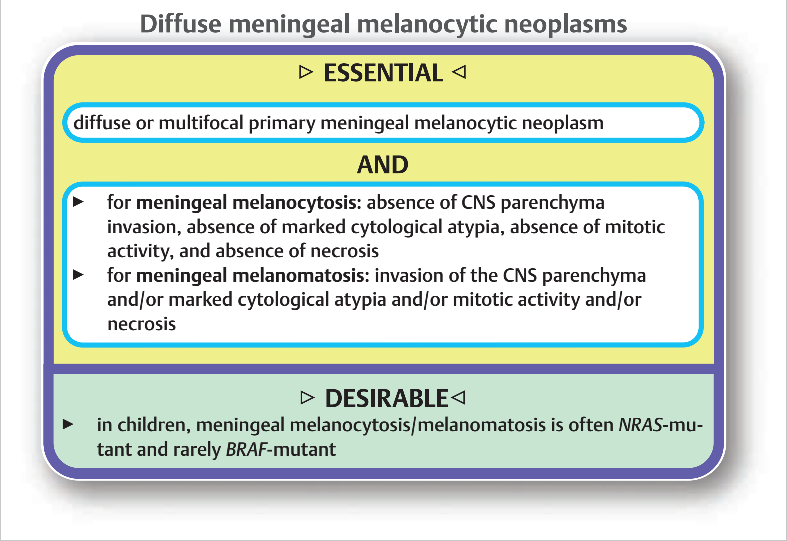
Meningeal melanocytosis

A diffuse or multifocal proliferation of cytologically bland melanocytic cells. See ▶ Fig. 48.1 for diagnostic criteria. May spread into perivascular spaces without invasion of the brain. Symptoms related to meningeal melanocytosis will develop in 10-15% of patients with large congenital cutaneous melanocytic nevi. Meningeal melanocytosis may be asymptomatic.

Prognosis is poor once symptoms manifest.

Meningeal melanomatosis

Malignant histology distinguishes these tumors from meningeal melanocytosis. CNS invasion is a common finding. See ▶ Fig. 48.1 for diagnostic criteria. Usually aggressive with poor prognosis.



Diffuse meningeal melanocytic neoplasms

▷ **ESSENTIAL** ◁

diffuse or multifocal primary meningeal melanocytic neoplasm

AND

- for **meningeal melanocytosis:** absence of CNS parenchyma invasion, absence of marked cytological atypia, absence of mitotic activity, and absence of necrosis
- for **meningeal melanomatosis:** invasion of the CNS parenchyma and/or marked cytological atypia and/or mitotic activity and/or necrosis

▷ **DESIRABLE** ◁

- in children, meningeal melanocytosis/melanomatosis is often *NRAS*-mutant and rarely *BRAF*-mutant

Fig. 48.1 Diagnostic criteria for diffuse meningeal melanocytic neoplasms. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

48.1.3 Circumscribed meningeal melanocytic neoplasms

General information

These tumors arise from leptomeningeal melanocytes and vary from well-differentiated neoplasms (meningeal melanocytoma) to aggressive, malignancies (meningeal melanoma). An intermediate grade between the two exhibits bland cytology but increased mitotic activity on invasion of parenchyma.

Diagnostic criteria for circumscribed meningeal melanocytic neoplasms

Diagnostic criteria for circumscribed meningeal melanocytic neoplasms are shown in ► Fig. 48.2.[3]

Meningeal melanocytoma

A well developed, solid, nonfinfiltrating melanocytic tumor that arises from the leptomeninges characterized by epithelioid fusiform, polyhedral or spindled melanocytes with no evidence of anaplasia, necrosis or increased mitoses. Rare reports of malignant transformation.[4] See ► Fig. 48.2 for diagnostic criteria.

Comprises 0.06–0.1% of brain tumors with an estimated incidence of 1 per 10 million.[5] Most commonly found in the cervical or thoracic spine. Less commonly, they originate in the leptomeninges of the posterior fossa or supratentorial intracranial compartment. A handful of patients with nevus of Ota (AKA oculodermal melanocytosis, which results from incomplete migration of melanocytes from the neural crest to the epidermis) have concurrent meningeal melanocytoma.[6]

Meningeal melanoma

A primary solitary malignant neoplasm that arises from leptomeningeal melanocytes characterized by aggressive growth. Histologically similar to melanomas occurring elsewhere.[5] See ► Fig. 48.2 for diagnostic criteria.

Circumscribed meningeal melanocytic neoplasms

▷ ESSENTIAL ◁

circumscribed/localized primary melanocytic neoplasm in the meninges

AND

- for **melanocytoma:** limited cytological atypia, (almost) no mitoses, no necrosis, and (in cases of evaluable CNS parenchyma) no CNS invasion
- for **intermediate-grade melanocytoma:** mitotic count[a] of 0.5–1.5 mitoses/mm^2 and/or CNS invasion, but limited cytological atypia and no necrosis
- for **melanoma:** mitotic count[a] > 1.5 mitoses/mm^2 and/or necrosis, often accompanied by marked cytological atypia

▷ DESIRABLE ◁

- demonstration of *GNAQ*, *GNA11*, *PLCB4*, or *CYSLTR2* mutation corroborates the CNS origin of the neoplasm, especially after exclusion of uveal or blue nevus–like melanoma
- additional molecular markers (*SF3B1*, *EIF1AX*, and *BAP1* mutations; chromosome 3 monosomy; complex copy-number variations) indicating aggressive behavior

[a] 1 mm^2 equates approximately to 5 HPF of 0.5 mm in diameter and 0.2 mm^2 in area.

Fig. 48.2 Diagnostic criteria for circumscribed meningeal melanocytic neoplasms. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Compared to melanocytoma, these are more pleomorphic, anaplastic, mitotically active and often invade CNS tissue and may demonstrate necrosis. May spread through CSF pathways. Occasional systemic metastases outside the CNS occur.[7]

Incidence of 0.5 per 10 million.[8] The peak age for this tumor is in the 4th decade (mean age: 43 years) compared to the 7th decade for primary cutaneous melanoma.[9]

They are aggressive and resistant to XRT. However, with GTR, the prognosis is better than with cutaneous melanoma metastatic to the CNS.

48.2 Germ cell tumors of the CNS

48.2.1 General information

Background

A family of morphological and immunophenotypic homologues of germ cell tumors of the gonads and other sites.

80-90% of GCTs occur in the midline, usually in the suprasellar and/or pineal region (simultaneous suprasellar and pineal region lesions is diagnostic of a GCT; so-called synchronous germ cell tumors, which comprise 13% of GCTs). GCTs are highly sensitive to XRT.[10] In the pineal region, these tumors occur predominantly in males. In females, GCTs are more common in the suprasellar region.[11] Aside from benign teratomas, all intracranial GCTs are malignant and may metastasize via CSF and systemically.

Epidemiology

GCTs primarily affect children and adolescents. They comprise 2–3% of primary intracranial tumors. Prevalence appears higher in eastern Asia.

Peak incidence: age 10–14 years. Affects males more than females, although in the suprasellar region girls are more prevalent.

CSF tumor markers

GCTs can (but not always) give rise to tumor markers in the CSF (see Tumor markers used clinically (p. 634)). ▶ Table 48.1 summarizes these findings.

- beta-human chorionic gonadotropin (β-hCG): elevated CSF levels are classically associated with choriocarcinomas, but also occur in up to 50% of germinomas (which are more common)
- alpha-fetoprotein (AFP) is elevated with yolk sac tumors, embryonal carcinoma and occasionally with teratomas
- placental alkaline phosphatase (PLAP) may be elevated in serum or CSF with intracranial germinomas[12]

NB: tumor markers alone are no longer considered useful for making a definitive diagnosis or following response to treatment with a pineal region tumor since many of these tumors are mixed cell type and many pineal region tumors do not give rise to markers.

Table 48.1 Occurrence of CSF tumor markers with pineal germ cell tumors

Tumor	β-hCG[a]	AFP	PLAP[b]
choriocarcinoma	≈ 100%	–	–
germinoma	10–50%	–	+
embryonal carcinoma	–	+	–
yolk sac carcinoma	–	+	–
immature teratoma	–	+	–
mature teratoma	–	–	–

[a] abbreviations: β-hCG = beta human chorionic gonadotropin, AFP = alpha-fetoprotein, PLAP = placental alkaline phosphatase

[b] elevated PLAP may also occur in serum

▶ **General outline of GCTs.** This outline shows the hierarchy of germ cell tumors. Details are provided in following sections.

1. germinoma: malignant tumor of primitive germ cells that occurs in the gonads (called testicular seminomas in males, dysgerminomas in females) or in the CNS. Survival with these is much better than with nongerminomatous tumors
   - *variant*: syncytiotrophoblastic giant cell variant
2. nongerminomatous germ cell tumors (NGGCT) include:
   a) embryonal carcinoma:
   b) choriocarcinoma
   c) yolk sac tumor AKA endodermal sinus tumor (EST): usually malignant
   d) teratoma. A germ cell tumor composed of at least two of the three germ cell layers: ectoderm, endoderm, and mesoderm. Subclassifications:
      - mature teratoma: adult-type tissue elements. Minimal mitoses. All 3 skin layers
      - immature teratoma: contain immature embryonic or fetal tissue alone or in combination with mature tissues
      - teratoma with somatic-type malignancy: contain a component resulting from malignant transformation of a somatic tissue (usually a carcinoma or sarcoma)
3. mixed germ cell tumor

48.2.2 Mature teratoma

General information

Exclusively comprised of mature somatic tissue, consisting of 2 or more of the 3 skin layers:

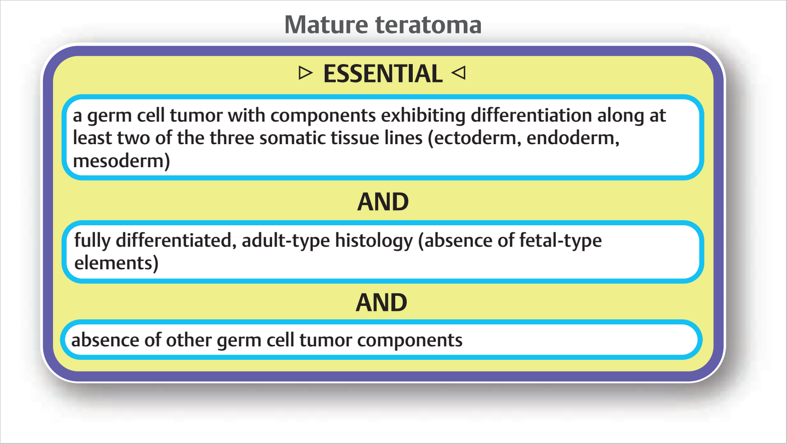
1. endoderm: glands lined with respiratory or enteric epithelia (often as dilated cysts) are typical, and rarely GI and bronchial structures, and hepatic or pancreatic tissue

2. mesoderm: smooth and striated muscle, cartilage and bone
3. ectoderm: epidermis, skin appendage organs (sweat glands, hair follicles often with hair), CNS tissue, choroid plexus, salivary gland

Little or no mitotic activity. Ki-67 in the mature tissue may be unexpectedly high.

Diagnostic criteria for mature teratoma

Diagnostic criteria for mature teratoma are shown in ▶ Fig. 48.3.[3]



Mature teratoma

▷ ESSENTIAL ◁

a germ cell tumor with components exhibiting differentiation along at least two of the three somatic tissue lines (ectoderm, endoderm, mesoderm)

AND

fully differentiated, adult-type histology (absence of fetal-type elements)

AND

absence of other germ cell tumor components

Fig. 48.3 Diagnostic criteria for mature teratoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

48.2.3 Immature teratoma

General information

The presence of any incompletely differentiated or fetal-like tissue requires the tumor to be designated as immature teratoma. Hypercellular stromal elements resembling fetal gut and respiratory tissue with increased mitotic activity are common. Other unusual components may include primitive retinal tissue or neural tube elements.

Diagnostic criteria for immature teratoma

Diagnostic criteria for immature teratoma are shown in ▶ Fig. 48.4.[3]

48.2.4 Teratoma with somatic-type malignancy

General information

Somatic cancers that may occur include rhabdomyosarcomas and undifferentiated sarcomas, adenocarcinoma resembling GI tract lineage and squamous cell carcinoma. Other rare cancers may also be seen. The diagnosis of somatic-type malignancy should not be made based on cytologic atypia alone.

Diagnostic criteria for teratoma with somatic-type malignancy

Diagnostic criteria for teratoma with somatic-type malignancy are shown in ▶ Fig. 48.5.[3]

Immature teratoma

▷ **ESSENTIAL** ◁

identification of incompletely differentiated elements exhibiting differentiation along at least two of the three somatic tissue lines (ectoderm, endoderm, mesoderm) in a teratoma, or the identification of any such elements within a tumor otherwise qualifying as a mature teratoma

AND

absence of other germ cell tumor components

Fig. 48.4 Diagnostic criteria for immature teratoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Teratoma with somatic-type malignancy

▷ **ESSENTIAL** ◁

identification of a distinct histological component that has the cytological features, architecture, mitotic activity, and disorderly growth pattern expected of a sarcoma, carcinoma, or other defined type of somatic cancer in a mature or immature teratoma

Fig. 48.5 Diagnostic criteria for teratoma with somatic-type malignancy. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

48.2.5 Germinoma

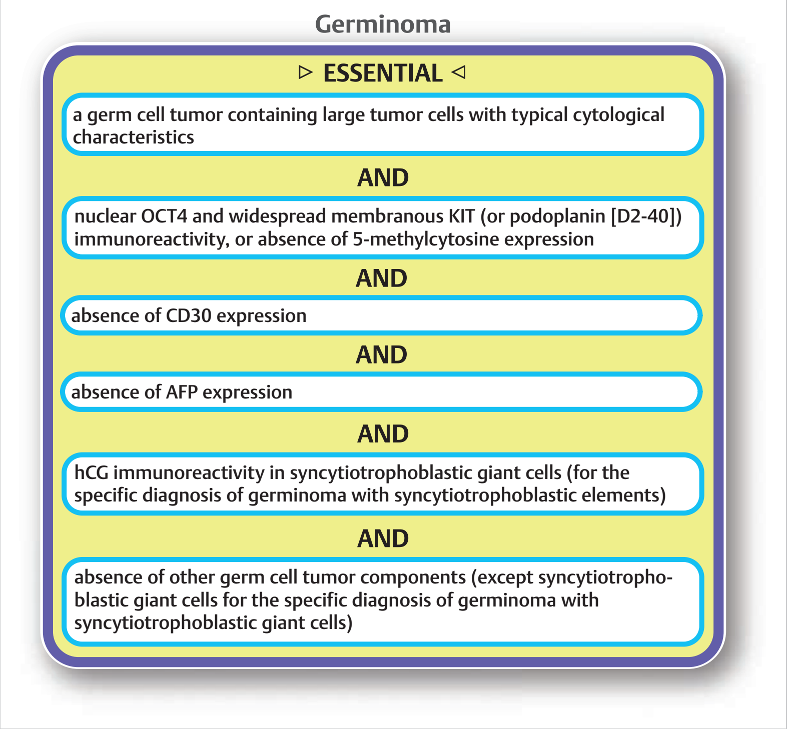
General information

Large, undifferentiated appearing cells resembling primordial germ cells with ample glycogen-rich clear cytoplasm containing round, vesicular and centrally place nuclei. The cells are arranged in sheets, lobules or cords with trabeculae. Necrosis is uncommon and mitotic activity is variable.

Some may have syncytiotrophoblastic giant cells seen on squash or smear preparations, but this alone does not qualify them as choriocarcinoma.

Diagnostic criteria for germinoma

Diagnostic criteria for germinoma are shown in ▶ Fig. 48.6.[3]



Germinoma

▷ ESSENTIAL ◁

a germ cell tumor containing large tumor cells with typical cytological characteristics

AND

nuclear OCT4 and widespread membranous KIT (or podoplanin [D2-40]) immunoreactivity, or absence of 5-methylcytosine expression

AND

absence of CD30 expression

AND

absence of AFP expression

AND

hCG immunoreactivity in syncytiotrophoblastic giant cells (for the specific diagnosis of germinoma with syncytiotrophoblastic elements)

AND

absence of other germ cell tumor components (except syncytiotrophoblastic giant cells for the specific diagnosis of germinoma with syncytiotrophoblastic giant cells)

Fig. 48.6 Diagnostic criteria for germinoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

48.2.6 Embryonal carcinoma

General information

Large epithelioid cells resembling cells of the embryonic germ disc containing vesicular nuclei, macronuclei and clear to violet cytoplasm. Mitotic activity is often increased. Necrotic areas are common.

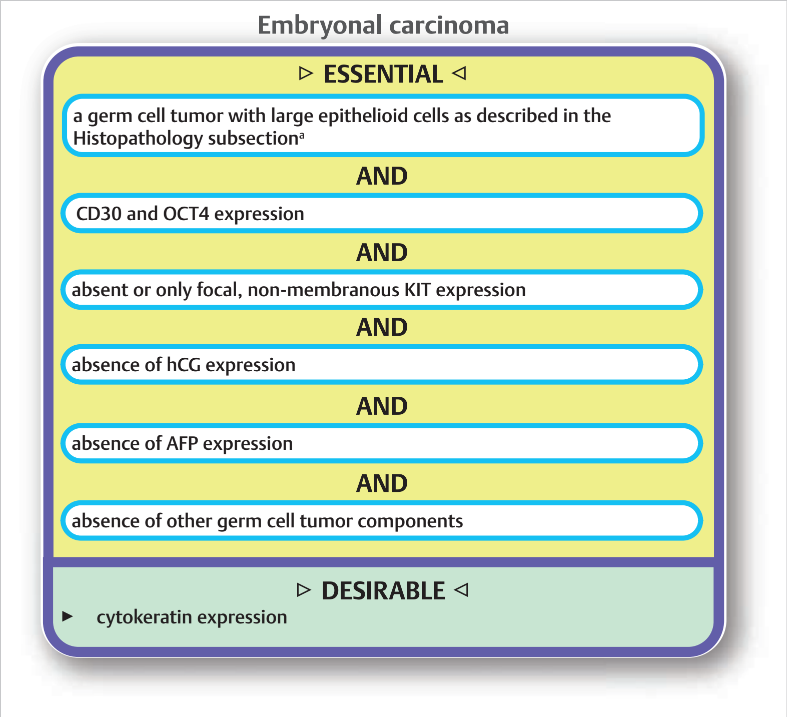
Diagnostic criteria for embryonal carcinoma

Diagnostic criteria for embryonal carcinoma are shown in ▶ Fig. 48.7.[3]

48.2.7 Yolk sac tumor

General information

Formerly called endodermal sinus tumor. Primitive appearing epithelial cells that may be associated with loose variably cellular stromal component. Bright eosiniphil PAS-positive particles may appear in the cytoplasm of epithelial cells but are not a consistent feature.



Embryonal carcinoma
▷ ESSENTIAL ◁
a germ cell tumor with large epithelioid cells as described in the Histopathology subsection[a]
AND
CD30 and OCT4 expression
AND
absent or only focal, non-membranous KIT expression
AND
absence of hCG expression
AND
absence of AFP expression
AND
absence of other germ cell tumor components
▷ DESIRABLE ◁
► cytokeratin expression

Fig. 48.7 Diagnostic criteria for embryonal carcinoma.
[a] For histopathology details, refer to the WHO blue book[3] (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Diagnostic criteria for yolk sac tumor

Diagnostic criteria for yolk sac tumor are shown in ► Fig. 48.8.[3] AFP (p. 635) reactivity in the cytoplasm distinguishes these tumors from other germ cell tumors except for yolk sac tumors and possibly the glandular and hepatocellular components of some teratomas.

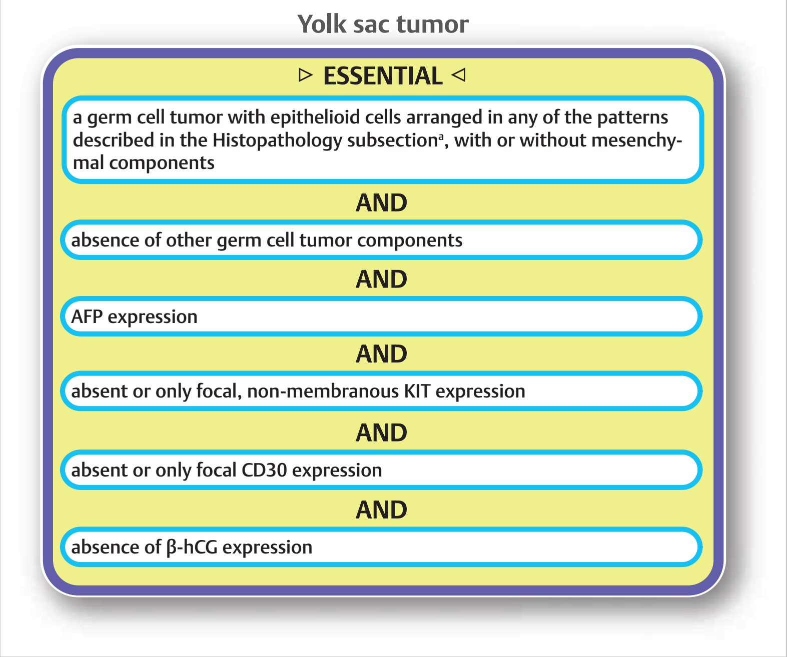
48.2.8 Choriocarcinoma

General information

Components of syncytiotrophoblast (the selective barrier between maternal and fetal blood in the placenta) are seen, characterized by giant cells that encompass cytotrophoblastic elements.

Diagnostic criteria for choriocarcinoma

Diagnostic criteria for choriocarcinoma are shown in ► Fig. 48.9.[3]



Yolk sac tumor
▷ ESSENTIAL ◁
a germ cell tumor with epithelioid cells arranged in any of the patterns described in the Histopathology subsection[a], with or without mesenchymal components
AND
absence of other germ cell tumor components
AND
AFP expression
AND
absent or only focal, non-membranous KIT expression
AND
absent or only focal CD30 expression
AND
absence of β-hCG expression

Fig. 48.8 Diagnostic criteria for yolk sac tumor.
[a] For histopathology details, refer to the WHO blue book[3] (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

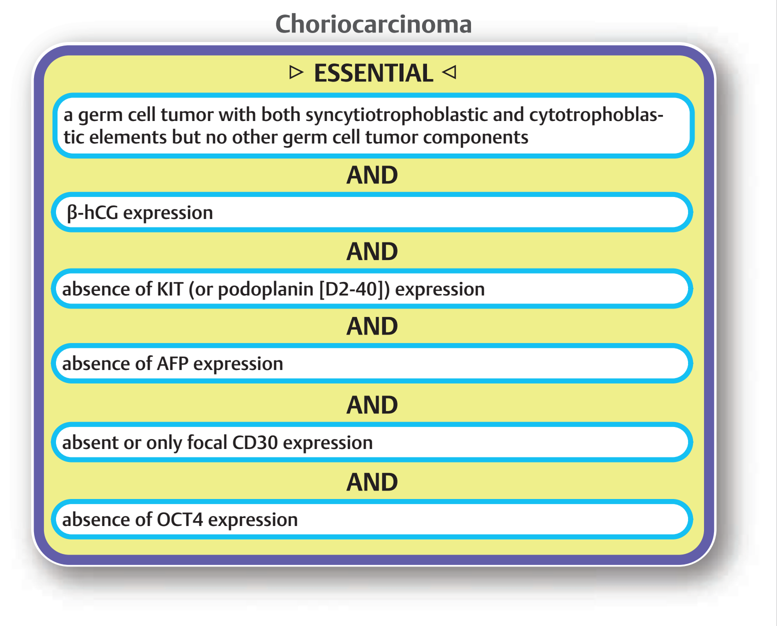
48.2.9 Mixed germ cell tumor

General information

Combinations of germ cell subtypes which exhibit the same findings as the subtypes in pure form.

Diagnostic criteria for mixed germ cell tumor

Diagnostic criteria for mixed germ cell tumor are shown in ▸ Fig. 48.10.[3]



Choriocarcinoma

▷ ESSENTIAL ◁

a germ cell tumor with both syncytiotrophoblastic and cytotrophoblastic elements but no other germ cell tumor components

AND

β-hCG expression

AND

absence of KIT (or podoplanin [D2-40]) expression

AND

absence of AFP expression

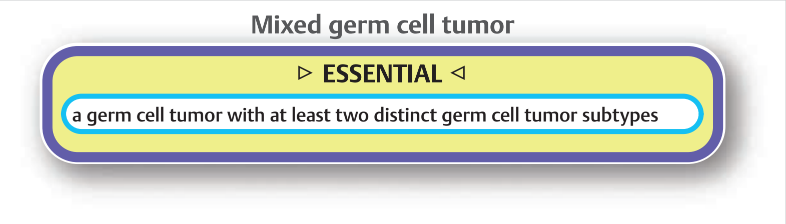
AND

absent or only focal CD30 expression

AND

absence of OCT4 expression

Fig. 48.9 Diagnostic criteria for choriocarcinoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)



Mixed germ cell tumor

▷ ESSENTIAL ◁

a germ cell tumor with at least two distinct germ cell tumor subtypes

Fig. 48.10 Diagnostic criteria for mixed germ cell tumor. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

49 Hematolymphoid Tumors Involving the CNS

49.1 CNS lymphomas

49.1.1 Primary diffuse large B-cell lymphoma of the CNS (CNS-DLBCL)

General information

Key concepts

- may be histologically identical to secondary secondary CNS spread of systemic DLBCL
- suspected with homogeneously enhancing lesion(s) in the central gray matter or corpus callosum (on MRI or CT) especially in AIDS patients
- may present with multiple cranial-nerve palsies
- diagnosis highly likely if tumor seen in conjunction with uveitis
- very responsive initially to steroids → short-lived disappearance (“ghost tumors”)
- treatment: usually XRT ± chemotherapy. Role of neurosurgery usually limited to biopsy and/or placement of ventricular access reservoir for chemotherapy, and occasionally to debulking an extremely large tumor causing severe symptoms
- risk factors: immunosuppression (AIDS, transplants), Epstein-Barr virus, collagen vascular diseases

AKA primary CNS lymphoma. CNS involvement with lymphoma may arise primarily, or may occur secondarily from a “systemic” lymphoma invading the CNS. CNS-DLBCL is a lymphoma confined to the CNS at presentation that has histological features and many molecular findings that replicate those of systemic lymphomas. 65% are solitary lesions, with the remainder being multifocal.

Diagnostic criteria for primary diffuse large B-cell lymphoma of the CNS (CNS-DLBCL)

Diagnostic criteria for CNS-DLBCL are shown in ▶ Fig. 49.1.[1]

Primary vs. secondary lymphoma

Secondary CNS lymphoma

Non CNS lymphoma is the fifth most common cause of cancer deaths in the U.S.; 63% of new cases are non-Hodgkin’s. Secondary CNS involvement usually occurs late in the course. Metastatic spread of systemic lymphoma to the cerebral *parenchyma* occurs in 1–7% of cases at autopsy.[2]

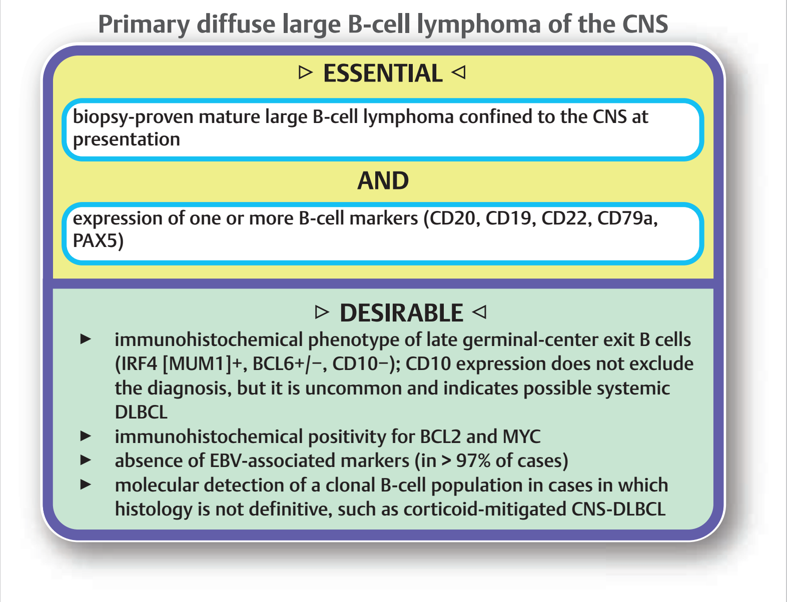
Primary CNS lymphoma

Older names include: reticulum cell sarcoma and microglioma,[3] since they were thought to possibly arise from microglia which were considered part of the reticuloendothelial system.

A rare, malignant primary CNS form of non-Hodgkin lymphoma comprising 0.85–2% of all primary brain tumors and 0.2–2% of malignant lymphomas.[4] May occasionally metastasize outside the CNS.

Specific types of primary CNS lymphoma

1. diffuse large B-cell lymphoma of the CNS (CNS-DLBCL): excludes any of lymphomas listed below, as well as lymphomas with systemic involvement
2. immunodeficiency-associated CNS lymphoma: immunodeficiency (includes immunosuppression for organ transplantation, IgA deficiency, SLE…) inceases the risk for lymphoma. Lymphoma associated with HIV or post-transplant immunosuppression is usually EBV-related
   a) AIDS-related diffuse large B-cell lymphoma
   b) EBV + diffuse large B-cell lymphoma, NOS
   c) lymphomatoid granulomatosis
3. intravascular large B-cell lymphoma
4. miscellaneous rare lymphomas in the CNS
   a) low-grade B-cell lymphomas



Primary diffuse large B-cell lymphoma of the CNS

▷ ESSENTIAL ◁

biopsy-proven mature large B-cell lymphoma confined to the CNS at presentation

AND

expression of one or more B-cell markers (CD20, CD19, CD22, CD79a, PAX5)

▷ DESIRABLE ◁

- immunohistochemical phenotype of late germinal-center exit B cells (IRF4 [MUM1]+, BCL6+/−, CD10−); CD10 expression does not exclude the diagnosis, but it is uncommon and indicates possible systemic DLBCL
- immunohistochemical positivity for BCL2 and MYC
- absence of EBV-associated markers (in > 97% of cases)
- molecular detection of a clonal B-cell population in cases in which histology is not definitive, such as corticoid-mitigated CNS-DLBCL

Fig. 49.1 Diagnostic criteria for CNS-DLBCL. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

    b) T-cell and NK/T-cell lymphomas
    c) anaplastic large cell lymphoma
5. extranodal marginal zone lymphoma of mucosa associated lymphoid tissue (MALT lymphoma) of the dura

Epidemiology

Incidence of primary CNS lymphoma (PCNSL) in the U.S.: 0.44 per 100,000,[5] making it the third most common of malignant primary brain tumors (behind GBM & diffuse astrocytoma). In the past 20 years, incidence has increased in patients > 60 years of age.[6]

Male:female ratio = 1.22:1.[5]

Median age at diagnosis: 52 yrs[7] (younger among immunocompromised patients: ≈ 34 yrs).

Most common supratentorial locations: frontal lobes, then deep nuclei; periventricular also common. Infratentorially: cerebellum is the most common location.

Conditions with increased risk of primary CNS lymphomas (PCNSL)

1. collagen vascular disease
    a) systemic lupus erythematosus
    b) Sjögren’s syndrome: an autoimmune connective tissue disorder
    c) rheumatoid arthritis
2. immunosuppression
    a) organ transplant recipients: related to chronic immunosuppression. Falls under category of post transplant lymphoproliferative disease (PTLD) (p. 845) [8]
    b) AIDS[9,10]: CNS lymphoma occurs in ≈ 10% of AIDS patients, and is the first presentation in 0.6%
    c) severe-congenital immunodeficiency syndrome (“SCIDS”)
    d) possibly increased incidence in the elderly due to reduced competency of immune system

3. Epstein-Barr virus[11] is associated with a broad spectrum of lymphoproliferative disorders, and is detectable in ≈ 30–50% of systemic lymphomas; however, it has been associated with almost 100% of PCNSL,[12] especially AIDS-related cases[13 (p 317)]

Presentation

General information

Presentation is similar with primary or secondary CNS lymphoma: the two most common neurologic manifestations are those due to epidural spinal cord compression and those of carcinomatous meningitis (multiple cranial nerve deficits) (p. 920). Seizures occur in up to 30% of patients.[14] Most lymphomas in patients first presenting with neurologic symptoms are PCNSL.[15]

Neurologic symptoms

1. presents with non-focal non-specific symptoms in over 50% of patients; at time of presentation most commonly includes:
   a) mental status changes in one–third
   b) symptoms of increased ICP (H/A, N/V)
   c) generalized seizures in 9%
2. focal symptoms in 30–42% of cases:
   a) hemimotor or hemisensory symptoms
   b) partial seizures
   c) multiple cranial-nerve palsies (due to carcinomatous meningitis)
3. combination of focal and non-focal symptoms

Signs

1. non-focal in 16%:
   a) papilledema
   b) encephalopathy
   c) dementia
2. focal findings in 45% of cases:
   a) hemimotor or hemisensory deficits
   b) aphasia
   c) visual field deficits
3. combination of focal and non-focal signs

Uncommon but characteristic syndromes

1. uveocyclitis, coincident with (in 6% of cases) or preceding the diagnosis of (in 11% of cases) lymphoma
2. subacute encephalitis with subependymal infiltration
3. MS-like illness with steroid-induced remission

Histology

Characteristic sites: corpus callosum, basal ganglia, periventricular.

The neoplastic cells are identical to those of systemic lymphomas. Most are bulky tumors that are contiguous with the ventricles or meninges.

Histologic distinguishing features: tumor cells form cuffs around blood vessels which demonstrate multiplication of basement membranes (best demonstrated with silver reticulum stain).

Frozen section distorts the cells and may lead to a misdiagnosis of malignant glioma.[13 (p 320)]

Immunohistochemical stains differentiate B-cell lymphomas from T-cell lymphomas (B-cell types are more common, especially in PCNSL and in AIDS).

EM shows absence of junctional complexes (desmosomes) that are usually present in epithelial derived tumors.

Intravascular lymphomatosis[16]: Formerly: (malignant) angioendotheliomatosis. A rare lymphoma with no solid mass in which malignant lymphoid cells are found in the lumen of small blood vessels in affected organs. CNS involvement is reported in most cases. Presentation is non specific: patients are often febrile, and may present with progressive multifocal cerebrovascular events (including stroke or hemorrhage), spinal cord or nerve root symptoms including cauda equina syndrome (p. 1254), encephalopathy, or peripheral or cranial neuropathies.[17] Initial transient cerebral symptoms may mimic TIAs or seizures. The ESR is often elevated prior to initiation of steroids. Lymphoma cells may be seen in the CSF.

Painful skin nodules or plaques occur in ≈ 10% of cases, generally involving the abdomen or lower extremities, and these cases may be diagnosed with skin biopsy (differential diagnosis here includes angioendotheliomatosis, a benign capillary, and endothelial cell disorder). Otherwise, diagnosis often requires brain biopsy (open or stereotactic), in which involved areas on imaging studies are targeted. Pathology: malignant lymphoid cells distend and occlude small arteries, veins and capillaries with little or no parenchymal extension.[13 (p 324)] Treatment with combination chemotherapy can result in long-term remission in some patients, but early diagnosis before permanent damage occurs is critical (diagnosis is rarely made pre-mortem).

Evaluation

All patients should be assessed (history, physical and laboratory tests as appropriate) for any of the conditions associated with lymphoma (p. 841). Since PCNSL is less common than secondary involvement, any patient with CNS lymphoma should have work-up for occult systemic lymphoma which may include:

1. careful physical exam of all lymph nodes (LN)
2. early detection of HIV and reflex CD4 + count nadir are important because HIV increases the risk of PCNSL and infection
3. contrast CT of chest, abdomen & pelvis or whole body PET/CT (evaluation of perihilar and pelvic LN)
4. routine blood (CBC, chemistries) and urine testing
5. LP for CSF (omit if not safe: anticoagulation, thrombocytopenia or intracranial mass effect): for routine tests (cell count, protein/glucose, culture) & cytology, flow cytometry
6. bone marrow biopsy
7. MRI of the entire spine
8. testicular ultrasound in males > 60 years of age (omit if PET scan is done and is negative)
9. ophthalmologic examination (including slit-lamp evaluation of both eyes) in all
    a) for possible uveitis
    b) ≈ 28% of patients with PCNSL will also have intraocular lymphoma. Often resistant to methotrexate, but responds to low dose ocular XRT (7–8 Gy)

Diagnostic tests

CT & MRI

▶ **Findings common to CT/MRI.** On imaging (CT or MRI) 50–60% occur in one or more cerebral lobes (in gray or white matter). 25% occur in deep midline structures (septum pellucidum, basal ganglion, corpus callosum). 25% are infratentorial. 10–30% of patients have multiple lesions at the time of presentation. In contrast, systemic lymphomas that spread to the CNS tend to present with leptomeningeal involvement instead of parenchymal tumors.[18]

Almost all PCNSLs enhance (except only 1.1% in immune intact, and 3.2% in immune compromised[5]).

Non–AIDS-related cases tend to enhance homogeneously, whereas AIDS-related cases are more likely to be ring-enhancing (necrotic center) and *multifocal*.[15,19]

Non–AIDS-related cases: CNS lymphomas should be suspected with homogeneously enhancing lesion(s) in the central gray or corpus callosum. 75% are in contact with ependymal or meningeal surfaces (this together with dense enhancement may produce a "pseudomeningioma pattern"; however, lymphomas lack calcifications and are more likely to be multiple).

▶ **CT (see also "Findings common to CT/MRI" above).** 60% are hyperdense to brain, only 10% are hypodense. Characteristically, > 90% of these tumors enhance; this is densely homogeneous in over 70%. As a result, when rare non-enhancing cases occur it often leads to a delay in diagnosis.[20] The appearance of enhanced PCNSL on CT has been likened to "fluffy cotton balls." There may be surrounding edema[21] and there is usually mass effect.

There is an almost diagnostic tendency of rapid partial to complete resolution on CT (and even at the time of surgery) following the administration of steroids, earning the nickname of "ghost-cell tumor"[15,22,23] or disappearing tumor.

▶ **MRI (see also "Findings common to CT/MRI" above).** No pathognomonic feature. Bright on DWI (restricted diffusion) in most cases, isointense to hypointense on ADC map. May be difficult to discern if tumor is located subependymally (signal characteristics similar to CSF); proton-weighted image may avoid this limitation.

Serologic tests

There are no blood tests that are diagnostic for PCNSL.

Serum lactate dehydrogenase (LDH) elevation indicates rapid cell turnover and is an independent poor prognosticator for non-Hodgkin, follicular and mantle cell lymphomas. In the absence of the diagnosis of lymphoma, this is nonspecific (occurs in liver failure, infection…).[15]

CSF studies

LP should only be performed if no mass effect. Some abnormality of routine CSF labs occurs in > 80%, but are non-specific. Most common abnormalities are elevated protein (in 45–67%), and increased cell count (in 40%). PCNSL can lower CSF glucose.[15]

Cytology is positive for lymphoma cells (preoperatively) in only 2–32%[15] (sensitivity may be higher with leptomeningeal involvement as in non-AIDS patients than with parenchymal involvement commonly seen in AIDS). Sensitivity is higher when **≥ 10.5 ml of CSF** is analyzed.[15] Repeating up to 3 LPs may increase yield. The morphology of lymphoma cells can sometimes be difficult to distinguish from inflammatory lymphocytes, but sharp nuclear notches, cytoplasmic irregularity, and increased cell size (> 2.5 times the upper limit of normal) are suggestive of lymphoma. Although the diagnosis of lymphoma can be made from CSF, cells obtained in this manner are not adequate for detailed tissue typing which is possible with solid tissue from biopsy, ∴ LP alone rarely suffices.

Flow cytometry provides information about the immunophenotype of lymphocytes.

Immunoglobulin analysis can show a single elevated immunoglobulin heavy chain (IgH) band with lymphoma, compared to a wide band produced by lymphocytes involved in an inflammatory process.[15]

Proteomics have shown elevated levels of antithrombin III in the CSF. A cutoff of levels > 1.2 mcg/dl is 75% sensitive and 98.7% specific.[24]

Angiography

Rarely helpful. 60% of cases show only an avascular mass. 30–40% show diffuse homogeneous staining or blush.

Treatment

Surgery

Surgical decompression with partial or gross total removal does not alter patient's prognosis. The main indication for surgery:

- biopsy: obtain solid tissue to ascertain that the tumor is a lymphoma, and to determine the type of lymphoma. Stereotactic techniques are often well-suited for these often deep tumors[25]

Radiation therapy

The standard treatment after tissue biopsy is whole-brain radiation therapy. Doses used tend to be lower than for other primary brain tumors. ≈ 40–50 Gy total are usually given in 1.8–3 Gy daily fractions.

Chemotherapy

General information

In *non-AIDS* cases, chemotherapy combined with XRT prolongs survival compared to XRT alone.[26]

Methotrexate (MTX)

The addition of intraventricular MTX (rather than just intrathecal via LP) delivered through a ventricular access device (6 doses of 12 mg twice a week, with IV leucovorin rescue) may result in even better survival.[27] In the event of an intrathecal MTX overdose (OD), interventions recommended[28]: ODs of up to 85 mg can be well tolerated with little sequelae; immediate LP with drainage of CSF can remove a substantial portion of the drug (removing 15 ml of CSF can eliminate ≈ 20–30% of the MTX within 2 hrs of OD). This can be followed by ventriculolumbar perfusion over several hours using 240 ml of warmed isotonic preservative-free saline entering through the ventricular reservoir and exiting through a lumbar subarachnoid catheter. For major OD of > 500 mg, add intrathecal administration of 2,000 U of carboxypeptidase G2 (an enzyme that inactivates MTX). In cases of MTX OD, systemic toxicity should be prevented by treating with IV dexamethasone and IV (not IT) leucovorin.

Rituximab

Available since 1997 for treatment of refractory systemic B-cell non-Hodgkins lymphoma. Intrathecally, may be more effective for CD33 + lymphomas.

Prognosis

With no treatment, median survival is 1.8–3.3 months following diagnosis.

With radiation therapy,[14] median survival is 10 months, with 47% 1-year median survival, and 16% 2-year median survival. 3-year survival is 8%, and 5-year survival is 3–4%. With intraventricular MTX, median time to recurrence was 41 mos.[27] Occasionally, prolonged survival may be seen.[29]

About 78% of cases recur, usually ≈ 15 months after treatment (late recurrences also are seen). Of these recurrences, 93% are confined to the CNS (often at another site if the original site responded well), and 7% are elsewhere.

Although there are individual studies that show trends, there are no prognostic features that consistently correlate with survival.

49.1.2 Immunodeficiency-associated CNS lymphomas (IDA-CNSL)

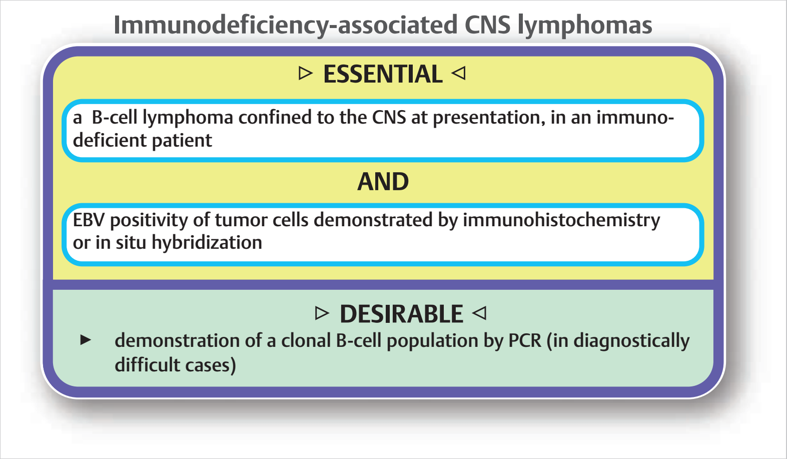
General information

A family of CNS lymphomas occurring in patients with inherited or acquired immunodeficiency (HIV AIDS, immunosuppression…). The number of cases related to AIDS has declined due to the effectiveness of newer anti-retroviral therapy. Most immunodeficiency-associated lymphomas are Epstein-Barr virus (EBV) related. EBV-positive DLBCL of the elderly is coupled with immunosenescence and starts to ramp up after age 50 years.[30]

Imaging demonstrates multiplicity of lesions and necrotic areas more frequently than in immunocompetent patients.

Diagnostic criteria for immunodeficiency-associated CNS lymphomas (IDA-CNSL)

Diagnostic criteria for IDA-CNSL are shown in ▶ Fig. 49.2.[1]



Immunodeficiency-associated CNS lymphomas

▷ ESSENTIAL ◁

a B-cell lymphoma confined to the CNS at presentation, in an immunodeficient patient

AND

EBV positivity of tumor cells demonstrated by immunohistochemistry or in situ hybridization

▷ DESIRABLE ◁

- demonstration of a clonal B-cell population by PCR (in diagnostically difficult cases)

Fig. 49.2 Diagnostic criteria for IDA-CNSL. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Prognosis

The prognosis is worse than CNS-DLBCL. Although complete remission occurs in 20–50% following XRT, the median survival is only 3–5 months,[31,32] usually related to AIDS-related opportunistic infection. However, neurologic function and quality of life improve in ≈ 75%.[31]

49.2 Histiocytic tumors

49.2.1 General information

Histiocytic disorders may be classified as follows:

1. malignant (true histiocytic lymphoma)
2. reactive (benign histiocytosis)
3. Langerhans cell histiocytosis (LCH)
    a) **unifocal**: formerly eosinophilic granuloma and/or histiocytosis X. Rare (1/1200 new cases/yr in US). More common in children. Slowly progressing disease. May occur in bone, skin, lungs, or stomach (see below)
    b) **multifocal unisystem**: seen mostly in children. Fever, bone & skin lesions
    c) **multifocal multisystem**: formerly Letterer-Siwe disease (a fulminant, malignant lymphoma of infancy).[33] Hand-Schüller-Christian triad: DI (from invasion of pituitary stalk), exophthalmos (from intraorbital tumor), and lytic bone lesions (particularly of cranium).
4. Erdheim-Chester disease
5. Rosai-Dorfman disease
6. juvenile xanthogranuloma
7. histiocytic sarcoma

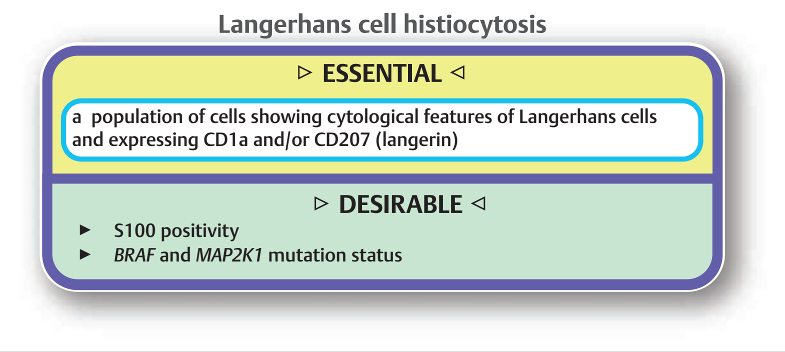
49.2.2 Langerhans cell histiocytosis of the CNS or meninges

General information

Formerly histiocytosis X (or eosinophilic granuloma, when solitary). A clonal proliferation of Langerhans-type cells involving the CNS, skull or meninges, with or without extra-CNS lesions. 36% of patients develop a leukoencephalopathy pattern, and 8% demonstrate cerebral atrophy.

Diagnostic criteria for Langerhans cell histiocytosis

Diagnostic criteria for Langerhans cell histiocytosis are shown in ► Fig. 49.3.[1]



Langerhans cell histiocytosis

▷ ESSENTIAL ◁

a population of cells showing cytological features of Langerhans cells and expressing CD1a and/or CD207 (langerin)

▷ DESIRABLE ◁

- S100 positivity
- *BRAF* and *MAP2K1* mutation status

Fig. 49.3 Diagnostic criteria for Langerhans cell histiocytosis. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Location

There is a predilection for the craniofacial bones and skull base (56%) favoring the parietal and frontal bones.[33] Intracranial involvement may include the hypothalamic-pituitary region (25-50%), meninges (30%) and choroid plexus (6%).[1]

Epidemiology

Generally a condition of youth, 70% of patients are < 20 yrs of age. In a series of 26 patients,[33] age range was 18 mos-49 yrs (mean: 16 yrs). The incidence among patients < 15 years old is 0.5 per 100,000, with a M;F ratio of ≈ 1:2.[34]

Clinical

Most common presenting symptom: *tender*, enlarging skull mass (> 90%). May be asymptomatic and incidentally discovered on skull X-ray obtained for other reasons. Blood tests were normal in all except 1 who had eosinophilia of 23%.

Evaluation

Skull X-rays

Classic radiographic finding: round or oval non-sclerotic punched out skull lesion with sharply defined margins, involving both inner and outer tables (the disease begins in diploic space), often with bevelled edges. A central bone density is occasionally noted (rare, but diagnostic). No abnormal vascularity of adjacent bone. No periosteal reaction. Differentiate from hemangioma by absence of sunburst appearance.

CT scan

Characteristic appearance of a soft tissue mass within area of bony destruction having a central density.[35] Differentiate from epidermoid, which has dense surrounding sclerosis.

Pathology

Gross: pinkish gray to purple lesion extending out of bone and involving pericranium. Dural involvement occurs in only 1 of 26 patients, but with no dural penetration.

Microscopic: numerous histiocytes, eosinophils, and multinucleated cells in a reticulin fiber network. No evidence that this is a result of an infection.

► **Molecular biology.** The most frequent molecular correlate if BRAF p.V600E mutation, seen in ≈ 50%.[1]

Treatment

There is a tendency toward spontaneous regression; however, most single lesions are treated by curettage. Multiple lesions are usually associated with extracalvarial bony involvement and are often treated with chemotherapy and/or low dose radiation therapy. Very radiosensitive.

Outcome

After a mean 8 years follow-up, 8 patients (31%) developed additional lesions, 5 of these were ≤ 3 yrs of age (all of 5 patients < 3 yrs of age)[33] (may suggest a form of multifocal LCH, thus young patients should be followed closely). Recurrences were local in one case, and in others involved other bones (including the skull, femur, lumbar spine) or brain (including the hypothalamus, presenting with diabetes insipidus and growth delay).

50 Tumors of the Sellar Region

50.1 General information

The pituitary gland is composed of the adenohypophysis, a neuroendocrine structure with 6 hormone secreting cell types, and the neurohypophysis which is comprised of pituicytes. Tumors can arise from these structures, and other tumors can occur in this region including those from rests of oral ectoderm (craniopharyngiomas) as well as meningiomas, germ cell tumors, chordomas and metastases.

50.2 Sellar region tumors of non pituitary origin

50.2.1 Craniopharyngiomas

Key concepts

- epithelial tumors thought to arise from residual cells of Rathke's pouch (p. 151)
- histologically benign, but the location and propensity to invade critical neural structures makes them malignant in behavior
- initially regarded as 1 tumor with two subtypes, now considered to be two distinct tumors which may be differentiated by gene mutations:
  1. adamantinomatous craniopharyngioma: 95% show *CTNNB1* mutations and aberrant nuclear expression of beta-catenin. Bimodal distribution: 5–15 years & 45–60 years
  2. papillary craniopharyngioma: 1–95% of cases show BRAF V600E mutations. Mean age of 40–55 years.

Historically, craniopharyngioma was considered a tumor with 2 subtypes, adamantinomatous and papillary. It is now recognized that, although both of these tumors arise in the same region and display squamous lineage, that they are actually discinct tumors with differing epidemiology, radiology, histology, and molecular genetics.[1]

They are thought to develop from residual cells of Rathke's pouch (p. 151) (craniopharyngeal duct).

CP do not undergo malignant degeneration, but the fact that they may infiltrate neural tissue can make them difficult to cure (benign in histology, malignant in behavior). CP are distinct from Rathke's cleft cyst (p. 949), but share some similarities.

Epidemiology

0.8% of all brain tumors, with an incidence of 0.19 per 100,000 in the US.[2] They comprise 5–11% of pediatric brain tumors, making them the most common non-neuroepithelial intracerebral tumor in children.

50.2.2 Adamantinomatous craniopharyngioma (ACP) (WHO grade 1)

General information

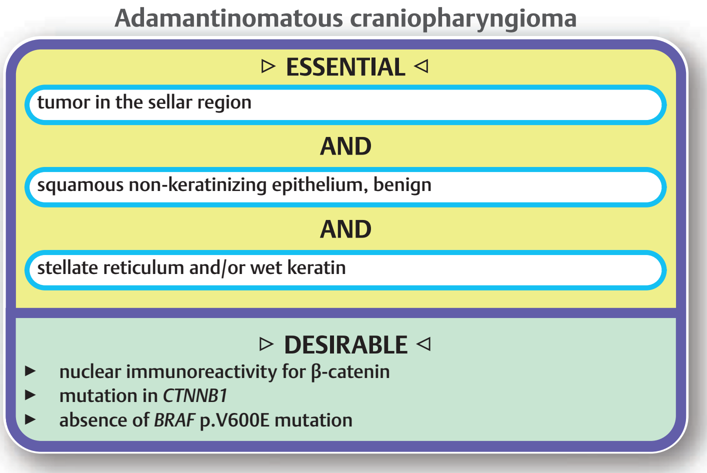
A mixed solid and cystic squamous epithelial tumor with stellate reticulum, wet keratin and basal pallisades. Up to 95% of cases of this variant shows *CTNNB1* mutations and aberrant nuclear expression of beta-catenin.[3] Tend to arise from the anterior superior margin of the pituitary. Fluid in the cysts varies, but usually contains cholesterol crystals.

Diagnostic criteria for adamantinomatous craniopharyngioma

Diagnostic criteria for adamantinomatous craniopharyngioma are shown in ▶ Fig. 50.1.[4]

Epidemiology

Bimodal age distribution: childhood peak age 5–15 years, adult peak age 45–60 years.[3]



Adamantinomatous craniopharyngioma

▷ **ESSENTIAL** ◁

tumor in the sellar region

AND

squamous non-keratinizing epithelium, benign

AND

stellate reticulum and/or wet keratin

▷ **DESIRABLE** ◁

- nuclear immunoreactivity for β-catenin
- mutation in *CTNNB1*
- absence of *BRAF* p.V600E mutation

Fig. 50.1 Diagnostic criteria for adamantinomatous craniopharyngioma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Location

Most occur in the region of the sella turcica and pituitary infundibulum. Purely sellar lesions are rare, with ≈ 95% extending into the suprasellar compartment. Pure involvement of the 3rd entricle is more common with papillary CP.

Imaging

Imaging mnemonic: “90% rule” 90% of adamantinomatous craniopharyngiomas exhibit at least 2 of the following “C” features: cyst formation, prominent calcifications, and contrast enhancement in the cyst walls.[5]

50.2.3 Papillary craniopharyngioma (RCP) (WHO grade 1)

General information

A craniopharyngioma with papillary features that occurs primarily in adults. 81–95% of cases show *BRAF* V600E mutations.[3] Usually solid, or partially cystic.

Diagnostic criteria for papillary craniopharyngioma

Diagnostic criteria for papillary craniopharyngioma are shown in ► Fig. 50.2.[4]

Location

Typically arises in the infundibular recess and tuber cinereum of the floor of the 3rd ventricle. Rarely occurs intrasellar.

Epidemiology

Comprise 1.2-4.6% of intracranial tumors, with an incidence of 0.5-1.5 cases per 1 million.[4] They are less common than adamantinomatous CP, constituting only ≈ 10% of all CP, but 12-33% in adults.[4]

Occurs almost exclusively in adults with a mean age of 40–55 years.

Papillary craniopharyngioma

▷ ESSENTIAL ◁

tumor in the sellar region

AND

non-keratinizing mature squamous epithelium covering fibrovascular cores or a cyst wall

▷ DESIRABLE ◁

- immunoreactivity for BRAF p.V600E
- presence of *BRAF* p.V600E mutation
- absence of nuclear β-catenin immunoreactivity
- absence of *CTNNB1* mutation

Fig. 50.2 Diagnostic criteria for papillary craniopharyngioma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Imaging

Less frequently cystic than adamantinomatous CP. Usually spherical (c.f., lobulated) and infrequently contain calcifications. The pituitary stalk is often thickened.

50.2.4 Vascular anatomy

Arterial supply: usually small feeders from ACA and A-comm, or from ICA and P-comm (do not receive blood from PCA or BA-bifurcation unless blood supply of the floor of the third ventricle is parasitized).

50.2.5 Treatment options

GTR is associated with better PFS than STR alone, but the advantage of GTR over STR followed by adjuvant XRST is not as clear.[4]

BRAF and/or MEK inhibitors show promise in *BRAF* p.V600E–mutant papillary CP.[6]

50.2.6 Surgical treatment

Pre-op endocrinologic evaluation

As for pituitary tumor (p. 876). Hypoadrenalism may be corrected rapidly, but hypothyroidism takes longer; either condition can increase surgical mortality.

Approach

Usually via large right frontotemporal flap as low as possible along base of frontal fossa (lateral sphenoid wing rongeured/drilled). Approach to tumor is extra-axial, whether subfrontal or frontotemporal. *All* tumors should be aspirated (even if they appear solid radiographically). Then, with microscope, possible approaches include:

1. subchiasmatic: through space between optic nerves and anterior to chiasm. It was thought that a “prefixed chiasm” (i.e., congenitally short optic nerves with chiasm unusually close to the planum sphenoidale) was more common in patients with CP, making this approach more difficult.

However, in reality the chiasm is probably bowed anteriorly by the tumor within the third ventricle, giving the illusion of a prefixed chiasm in most cases
2. opticocarotid (between right ICA and right optic nerve/tract)
3. lamina terminalis (tumor often needs to be brought down and removed subchiasmatically)[7,8]
4. lateral to carotid artery
5. transfrontal-transsphenoidal: drill off tuberculum sellae

Alternative approaches to frontotemporal
1. pure transsphenoidal: if dark fluid is aspirated with no CSF evident, it is possible to leave a stent from the tumor cavity to the sphenoid air-sinus to permit continued drainage
2. transcallosal: strictly for tumors limited to the third ventricle
3. a combined subfrontal/pterional approach capitalizes on the advantages of each (head is positioned with slight lateral rotation)
4. extended transnasal transsphenoidal endoscopic resection[9,10]

Spare the following structures: small arterial feeders to *undersurface* of the chiasm (major supply) and tract; at least a remnant of pituitary stalk (recognized by unique pattern of longitudinal striations which are the long portal veins). If the tumor easily pulls down from above then this is permissible; however, do not pull too hard, or else hypothalamic injury may result.

Post-op
1. steroids: these patients are all considered hypo-adrenal. Give hydrocortisone in physiologic doses (for mineralocorticoid activity) in addition to dexamethasone (glucocorticoid that treats edema) taper. Taper steroids slowly to avoid aseptic (chemical) meningitis
2. diabetes insipidus (DI) (p. 902): often shows up early. May be part of a "triphasic response." (p. 125) Best managed initially with fluid replacement. If necessary, use short acting vasopressin (prevents iatrogenic renal shutdown if an SIADH-like phase develops during vasopressin therapy)

50.2.7 Radiation

Controversial. **Side effects:** include endocrine dysfunction, optic neuritis, dementia. Post-op XRT probably helps prevent regrowth when residual tumor is left behind[11]; however, in pediatric cases it may be best to postpone XRT (to minimize deleterious effect on IQ), recognizing that reoperation may be necessary for recurrence.

50.2.8 Outcome

Most outcome data are derived from CP as a monolithic entity, and since papillary CP make up only a minority of CPs, their outcome data is sparse. It has been asserted that papillary CP have a better prognosis, but inconvertible proof of this is lacking.

5–10% mortality in most series, most from hypothalamic injury (unilateral hypothalamic lesions are rarely clinically evident; bilateral injuries may produce hyperthermia and somnolence; damage to anterior osmoreceptors may → loss of thirst sensation).

Five year survival is ≈ 55–85% (range from 30–93% has been reported).

50.2.9 Recurrence

Most recurrences are in < 1 year, few > 3 yrs (very delayed recurrence usually follow what was thought to be "total" removal). Morbidity/mortality is higher with reoperation.

50.3 Tumors of the neurohypophysis & infundibulum

50.3.1 General information

Description

This group of rare low-grade tumors that originate from pituicytes of the neurohypophysis (posterior pituitary) and infundibulum are probably a spectrum of a single entity, the members of the group being:
1. pituicytoma
2. granular cell tumor of the sellar region (GCT)

3. spindle cell oncocytoma (SCO)

These tumors all show nuclear expression of thyroid transcription factor 1 (TTF1). They are usually misidentified as PitNET/adenomas on imaging, and are rarely considered in the preoperative differential diagnosis.

Epidemiology

The rarity of these tumors has prevented robust epidemiologic analysis. A literature meta-analysis of 270 cases[12] found a mean age of 48 ± 22 years.

Location

These tumors originate in the posterior pituitary or infundibulum, and therefore their location is purely sellar (25%), sellar with suprasellar extension (48%), or suprasellar (23%).[12] Spindle cell oncocytoma can be more invasive (see below).

Presentation

Symptoms from mass effect are similar to other tumors of this location: visual field defects (in 58%) (classically bitemporal hemianopsia), hypopituitarism (34%), and H/A (40%).[12] Diabetes insipidus occurs infrequently (2.4%).

Associated endocrinologic overproduction syndromes include hypercortisolism (4.1%), and acromegaly (2.0%), some of which may be due to synchronous functional PitNET/adenomas.[13]

Imaging

These tumors may appear radiographically identical to adenomas. They are rarely considered in the differential diagnosis pre-op. Isodense on CT and isointense on T1WI MRI, with dense homogeneous enhancement on CT and MRI.

Treatment

GTR frequently cures these tumors, although SCO appears to have a higher recurrence rate. If the diagnosis is suspected pre-op, a transcranial approach is preferred over transsphenoidal because of the vascularity which has prevented total resection in 60–70% of reported cases.[14]

XRT may be considered for subtotal resection.[15]

50.3.2 Pituicytoma (WHO grade 1)

General information

Rare (mostly case reports). Circumscribed, with bipolar spindle cells arranged in a fascicular or storiform pattern (a cartwheel pattern).[3,16] Low mitotic activity. Cytoplasmic granules (found in granular cell tumors) are lacking. WHO grade 1. Reported only in adults.

Diagnostic criteria for pituicytoma

Diagnostic criteria for pituicytoma are shown in ▶ Fig. 50.3.[4]

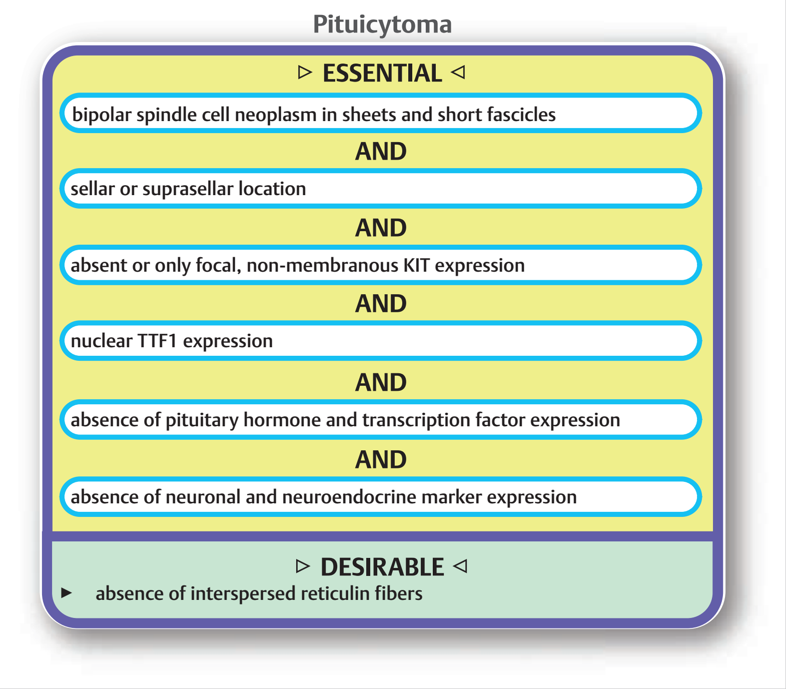
50.3.3 Granular cell tumor of the sellar region (WHO grade 1)

General information

A circumscribed tumor with nests of large cells having granular, eosinophilic cytoplasm due to copious cytoplasmic lysosomes. Mitotic activity is rare.

While rare, GCTs are the most common primary tumor of the neurohypophysis and pituitary stalk/infundibulum[15] with a predilection for the stalk (causing suprasellar extension). GCTs have been identified in the gastrointestinal tract, genitourinary tract, orbital region as well as in other locations of the central nervous system with no connection to the pituitary gland or hypothalamus (e.g., spinal meninges[17]). Female:male ratio ≥ 2:1. Asymptomatic microscopic clusters of granular cells (tumorettes) are more common, with an incidence up to 17%.[18]

They usually follow a slow progression with benign behavior.



Pituicytoma

▷ **ESSENTIAL** ◁

bipolar spindle cell neoplasm in sheets and short fascicles

AND

sellar or suprasellar location

AND

absent or only focal, non-membranous KIT expression

AND

nuclear TTF1 expression

AND

absence of pituitary hormone and transcription factor expression

AND

absence of neuronal and neuroendocrine marker expression

▷ **DESIRABLE** ◁

- absence of interspersed reticulin fibers

World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Diagnostic criteria for granular cell tumor

Diagnostic criteria for granular cell tumor are shown in ▶ Fig. 50.4.[4]

50.3.4 Spindle cell oncocytoma (WHO grade 1)

General information

In addition to intrasellar and suprasellar involvement, there are reports of invasion of the cavernous sinus[19] and floor of the sella.[20] Their highly vascular nature makes them suscepitble to spontaneous hemorrhage and also to significant blood loss during surgery.

Diagnostic criteria for spindle cell oncocytoma

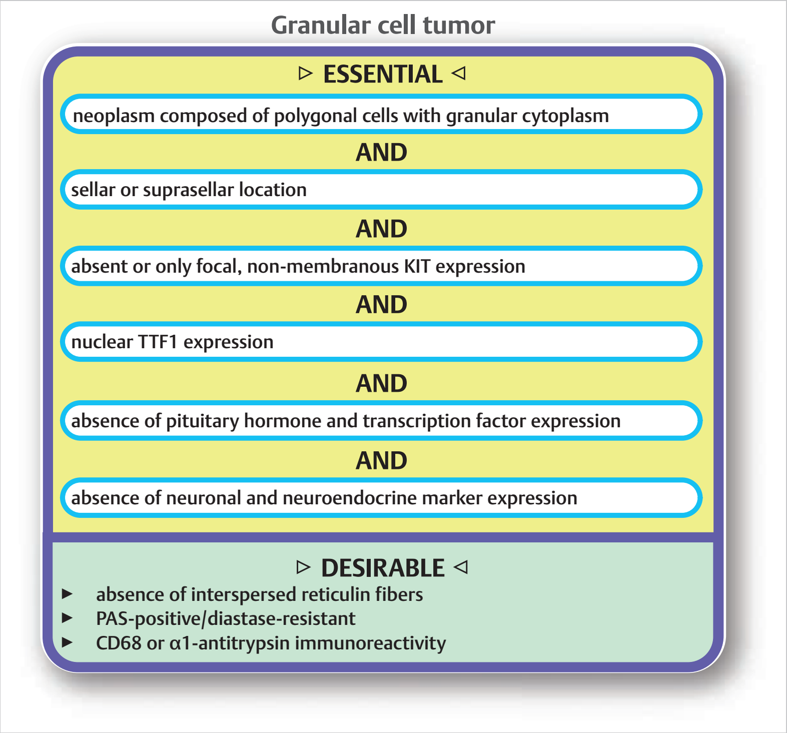
Diagnostic criteria for spindle cell oncocytoma are shown in ▶ Fig. 50.5.[4]

50.4 Tumors of the adenohypophysis

50.4.1 Pituitary neuroendocrine tumor (PitNET)/pituitary adenoma

General information

A clonal neoplasm of anterior pituitary hormone producing cells.



Granular cell tumor

▷ ESSENTIAL ◁

neoplasm composed of polygonal cells with granular cytoplasm

AND

sellar or suprasellar location

AND

absent or only focal, non-membranous KIT expression

AND

nuclear TTF1 expression

AND

absence of pituitary hormone and transcription factor expression

AND

absence of neuronal and neuroendocrine marker expression

▷ DESIRABLE ◁

- absence of interspersed reticulin fibers
- PAS-positive/diastase-resistant
- CD68 or α1-antitrypsin immunoreactivity

Fig. 50.4 Diagnostic criteria for granular cell tumor. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Terminology: traditionally, these tumors have been classified as adenomas, but they are actually neuroendocrine tumors since they contain neurosecretory granules. Thus the current nomenclature is pituitary neuroendocrine tumors (PitNETs). To transition the terminology, for the time being they may also be called **PitNET/adenomas** to denote that "pituitary adenoma" is still acceptable, but PitNET is preferred.[21]

Diagnostic criteria for PitNET/adenoma

Diagnostic criteria for PitNET/adenoma are shown in ▶ Fig. 50.6.[4]

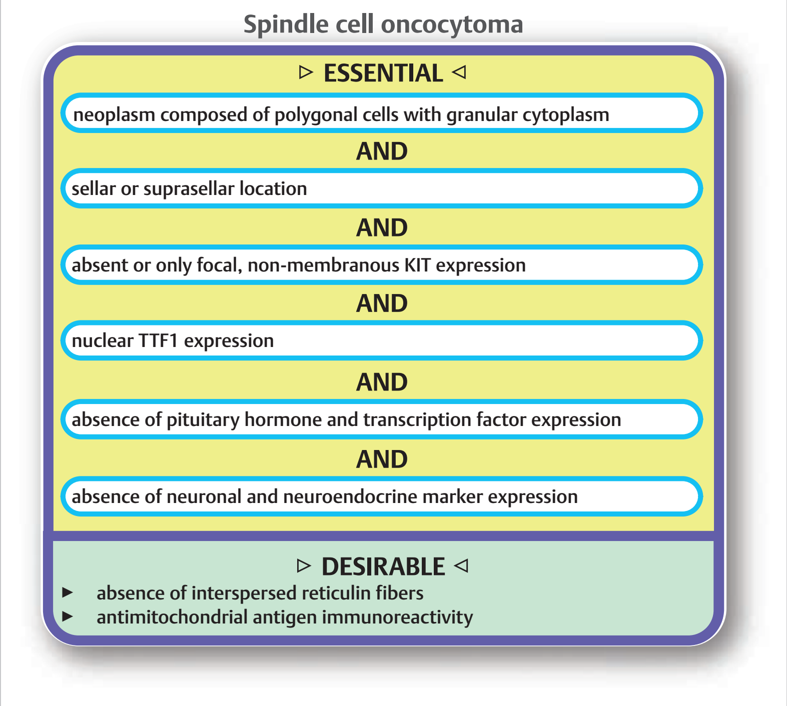
Clinical considerations for PitNET/adenomas

Owing to the intricacies of PitNET/adenomas, a number of sections are devoted to their clinical aspects, starting with section 51.

50.4.2 Invasive pituitary tumors

General information

Tumors of the anterior pituitary can invade surrounding structures. Some of these are PitNETs (≈ 5% of PitNETs, and ≈ 30-40% of *surgically treated* PitNETs are invasive[22]). Non-functioning PitNETs have a



Spindle cell oncocytoma

Fig. 50.5 Diagnostic criteria for spindle cell oncocytoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

higher incidence of invasion.[23] However, more aggressive pituitary tumors can also be locally invasive, and are considered here.

Wilson's anatomic classification for invasive pituitary tumors[24] (modified from Hardy[25,26]) is shown in ▶ Table 50.1.

At times, a pituitary tumor may displace the medial wall of the cavernous sinus ahead of it without actually perforating this dural structure (i.e., not actually invading the sinus).[27] This is difficult to reliably identify on MRI, and the most definitive sign of cavernous sinus invasion is carotid artery encasement.[28]

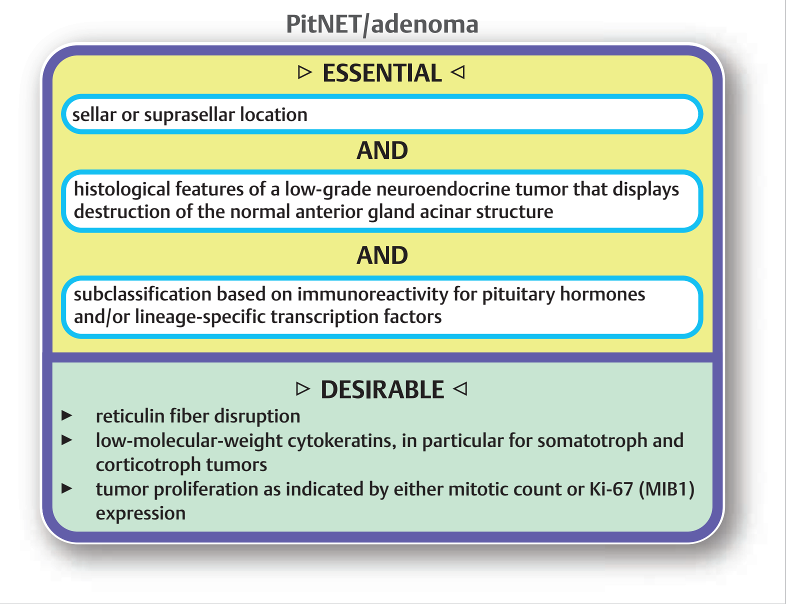
The clinical course is variable, with some tumors being more aggressive than others. Occasionally, these tumors grow to sizes > 4 cm dia, and these are often very aggressive and follow a malignant course.[29]

Aggressive pituitary tumors

A subset of invasive pituitary tumors meet the European Society of Endocrinology (ESE) guidelines[30] definition of "aggressive pituitary tumors," viz., pituitary tumors that do not respond to standard therapies (surgery, conventional medical treatments and XRT) and present with multiple local recurrences. The WHO does not recognize this category in its current classification[4] (and the term "atypical adenoma" was dropped in the WHO 2017 classification).

Pituitary carcinoma

The definition of pituitary carcinoma is contentious. Both the ESE and WHO consider the presence of noncontiguous metastases as qualifying as pituitary carcinoma.[4,21] Only ≈ 0.16% of pituitary tumors



PitNET/adenoma

▷ ESSENTIAL ◁

sellar or suprasellar location

▷ DESIRABLE ◁

- reticulin fiber disruption
- low-molecular-weight cytokeratins, in particular for somatotroph and corticotroph tumors
- tumor proliferation as indicated by either mitotic count or Ki-67 (MIB1) expression

Fig. 50.6 Diagnostic criteria for PitNET/adenoma. (Modified with permission from WHO Classification of Tumors Editorial Board, (ed.) World Health Organization classification of tumors of the central nervous system. 5th ed. Bosman F T, Jaffe E S, Lakhani S R, et al. (series eds.): World Health Organization Classification of Tumors series, vol. 6. International Agency for Research on Cancer, Lyon, France, 2021.)

Table 50.1 Anatomic classification of invasive pituitary tumors (modified Hardy system)[24]

Extension
• **Suprasellar extension** 0: none A: expanding into suprasellar cistern B: anterior recesses of 3rd ventricle obliterated C: floor of 3rd ventricle grossly displaced • **Parasellar extension** D[a]: intracranial (intradural) E: into or beneath cavernous sinus (extradural)
Invasion/Spread
• **Floor of sella intact** I: sella normal or focally expanded; tumor < 10 mm II: sella enlarged; tumor ≥ 10 mm • **Sphenoid extension** III: localized perforation of sellar floor IV: diffuse destruction of sellar floor • **Distant spread**[b] V: spread via CSF or blood-borne
[a]specify: 1) anterior, 2) middle, or 3) posterior fossa [b] this qualifies as pituitary carcinoma (see text)

give rise to noncontiguous metastases (spreading systemically or through the CSF).[31] Although the prognosis with metastases is worse, there are some aggressive tumors with similar behavior even in the absence of metastases.[22]

Nomenclature suggestion for pituitary tumor grades

Taking into account the areas of agreement and areas of uncertainty in classification, the suggestion shown in the box has been proposed[22,32]

Σ: Nomenclature suggestion for pituitary tumor grades[22,32]

- Noninvasive tumors on MRI (60-65%): **PitNET/adenomas**
- Invasive tumors on MRI (35-40%):
  - Persistent disease that is *controlled* (with or without XRT) after surgery and/or medical treatment: **Invasive PitNet**
  - Persistent disease that is *recurrent or progressive* (with or without XRT) after surgery and/or medical treatment[a]: **aggressive pituitary tumor** or **invasive PitNET with malignant potential**
  - Persistent disease with noncontiguous metastases[a]: **Pituitary carcinoma**

[a] many of these tumors will exhibit some combination of the following (only 2% exhibit all 3[33]): Ki67 ≥ 3%, positive P53 expression and/or mitotic rate > 2/10 HPF

Presentation of invasive pituitary tumors

1. visual system
   a) most present due to compression of the optic apparatus, usually producing gradual visual deficit (however, sudden blindness is not unheard of)
   b) extraocular muscle deficits may occur with cavernous sinus invasion, and usually develop after visual loss
   c) exophthalmos may occur with orbital invasion due to compromise of orbital venous drainage
2. hydrocephalus: suprasellar extension may obstruct one or both foramen of Monro
3. invasion of the skull base may lead to nasal obstruction. CSF rhinorrhea may occasionally be precipitated by tumor shrinkage in response to dopamine agonists (e.g., bromocriptine or cabergoline) as a result of uncovering areas of bone erosion. This carries the risk of ascending meningitis.[34]
4. invasive pituitary tumors that secrete prolactin (p. 863) often present with findings of hyperprolactinemia and with these, the prolactin levels are usually > 1000 ng/ml (caution: giant invasive adenomas with very high prolactin production may have a falsely low PRL due to "hook effect" (p. 877))

Management suggestions for invasive pituitary tumors

The European Society of Endocrinology (ESE) treatent guidelines include the following[30] (see reference for full details).

1. routine pituitary tumor screening ▶ Table 52.1 (pituitary hormone assessment and visual field testing)
2. the diagnosis of an aggressive pituitary tumor should be considered with invasive tumors exhibiting an unusually rapid growth rate, or clinically significant growth following optimal standard treatment (surgery, XRT and conventional medical treatment)
3. consider screening for metastatic disease for symptoms outside the sellar region or MRI findings suspicious for local noncontiguous spread
4. initial surgery by a surgeon with extensive experience in pituitary surgery
5. Ki67 proliferative index should be assessed in surgical specimens, and if the Ki67 is ≥ 3%, then p53 immunodetection and mitotic count should be evaluated as potential predictors of tumor aggressiveness
6. consideration of repeat surgery prior to proceeding to other treatment options
7. XRT
   a) recommended for progression after surgery for non-functioning tumors, or after surgery + standard medcial treatment in functioning tumors
   b) consideration of XRT recommended after surgery for clinically relevant tumor remnant with markers that suggest aggressive behavior (Ki67 ≥ 3% and/or positive P53 and/or mitotic rate > 2/10 HPF)

8. chemotherapy for tumors demonstrating continued growth*
    a) Stupp regimen (p. 672): temozolamide (TMZ) monotherapy using the *adjuvant* dosing regimen (150-200 mg/m^2 for 5 consecurive days every 28 days) & XRT (if maximal XRT has not yet been given)
    b) assessment after 3 cycles of TMZ
        1. if there is clinical response, continue TMZ cycles for 5 days every 28 days for 6 months total, and consideration for longer duration if continued benefit is demonstrated
        2. if no response, then a trial with systemic toxic chemotherapy is suggested (no specific agent could be preferentially recommended)
9. for isolated metastases, local regional therapies in addition to systemic treatment as indicated
10. MRIs should be repeated every 3-12 months depending on tumor growth and risk to vital structures

* assessment of MGMT promoter gene methylation (p. 673) expression is mentioned as a recommendation, but this may not alter the treatment paradigm.

51 PitNET/Adenomas – Clinical Considerations

51.1 General information

Key concepts

- most are benign, however some are locally aggressive and (rarely) metastasize
- presentation (p. 863): most common
    - symptoms from excess hormonal secretion: includes hyperprolactinemia, Cushing's syndrome (↑ cortisol), acromegaly (↑ growth hormone)…
    - mass effect. Most commonly: bitemporal hemianopsia from compression of optic chiasm, or infrequently hypopituitarism from compression of pituitary gland
    - H/A: some H/A are due to increased pressure within the sella
    - incidental finding
    - infrequent presentations: pituitary apoplexy (p. 865), spontaneous CSF rhinorrhea
- work-up for a newly diagnosed intrasellar lesion: endocrine screening, visual field evaluation, imaging to visualize the tumor, the parasellar carotid arteries and the sphenoid sinus (see ▶ Table 52.1)
- prolactinoma is the only type for which medical therapy (DA agonists) may be the primary treatment (p. 886). For other tumor types, options primarily consist of surgery (usually transsphenoidal, sometimes transcranial), or XRT
- post-op concerns include: diabetes insipidus, adrenal insufficiency, CSF leak, and rarely visual deterioration due to herniation of the optic chiasm into empty sella

See review of pituitary embryology and neuroendocrinology (p. 151), and, for a discussion of the change in classification to PitNET/adenomas as well as diagnostic criteria, see section 50.4.1.

Most primary pituitary tumors are benign and arise from the anterior pituitary gland (adenohypophysis) as a monoclonal proliferation. However, some can be locally aggressive and rarely may metastasize.

PitNETs have been classified by a number of schemes, including: by endocrine function (aided by immunostaining), by light microscopy (p. 871) with routine histological staining, by electron microscopic appearance, and by molecular biology.

Microadenoma: defined as a pituitary tumor ≤ 1 cm diameter. 50% of pituitary tumors are < 5 mm at time of diagnosis. These may be difficult to find at the time of surgery.

Macroadenomas: pituitary tumors > 1 cm diameter.

51.2 Diagnostic criteria and classification of PitNET/adenoma

Diagnostic criteria for PitNET/pituitary adenoma are shown in ▶ Fig. 50.6.[1]

PitNETs derive from the six adenhohypophyseal cell types. Each tumor type may have multiple subtypes which are shown along with their secretion products and clinical syndromes in ▶ Table 51.1

▶ **Null cell tumor (adenoma).** A PitNET without cell-type-specific differentiation based on immunohistochemistry, transcription factors, negative PAS stain.[3] The term is not synonymous with nonfunctioning adenomas. No endocrine syndrome is associated with these tumors. They comprise 5-30% of surgically resected adenomas, and < 5% of non-functioning adenomas. They typically occur after age 60 years.

51.3 Epidemiology/pathology

Pituitary tumors represent ≈ 10% of intracranial tumors (incidence is higher in autopsy series). They are most common in the 3rd and 4th decades of life, and affect both sexes equally. Nonfunctioning PitNETs are the most common pituitary tumors.[4] Cushing's disease and prolactinomas are more common in females, and nonfunctioning, lactotroph and null tumors[3] are more common in males.

Table 51.1 Classification of PitNETs[1,2] (used with permission from WHO Classification of Tumours Editorial Board. Central Nervous System Tumours. Lyon (France): International Agency for Research on Cancer; 2021. (WHO classification of tumours series, 5th ed.; vol. 6). Available from: https://tumourclassification.iarc.who.int/.)

Tumor type[a]	Transcription factors	Hormones	Keratin (CAM5.2 or CK18)	Tumor subtypes (if applicable)	Hormone excess syndrome[b]
PIT1-lineage tumors					
Somatotroph tumors	PIT1	GH, α-subunit	perinuclear	densely granulated somatotroph tumor	florid acromegaly
		GH	fibrous bodies (> 70%)	sparsely granulated somatotroph tumor	subtle acromegaly
Lactotroph tumors	PIT1, ERα	PRL (paranuclear)	weak or negative	sparsley granulated lactotroph tumor	hyperprolactinemia[c]
		PRL (diffuse cytoplasmic)	weak or negative	densely granulated lactotroph tumor	hyperprolactinemia[c]
Mammosomatotroph tumor	PIT1, ERα	GH (often predominant), PRL, α-subunit	perinuclear		acromegaly and hyperprolactinemia[c]
Thyrotroph tumor	PIT1, GATA2/3[d]	α-subunit, TSH-β	weak or negative		hyperthyroidism
Mature PIT1-lineage tumor	PIT1, ERα, GATA2/3[d]	GH (often predominant), PRL, α-subunit, TSH-β	perinuclear		acromegaly, hyperprolactinemia[c] and hyperthyroidism
Acidophil stem cell tumor	PIT1, ERα	PRL (predominant), GH (focal/variable)	scattered fibrous bodies		hyperprolactinemia[c] and subclinical acromegaly
Immature PIT1-lineage tumor	PIT1, ERα, GATA2/3[d]	GH, PRL, α-subunit, TSH-β	focal/ variable		acromegaly, hyperprolactinemia[c] and hyperthyroidism
TPIT-lineage tumors					
Corticotroph tumors	TPIT (TBX19), NeuroD1 (β2)	ACTH and other POMC derivatives	strong	densely granulated corticotroph tumor	florid Cushing, often microtumor
			variable	sparsely granulated corticotroph tumor	subtle Cushing, often macrotumor
			intense ring-like perinuclear	Crooke cell tumor	variable, Cushing
SF1-lineage tumors					
Gonadotroph tumor	SF1, ERα, GATA2/3[d]	α-subunit, FSH-β, LH-β	variable		hypogonadism (virtually all) or hypergonadism (exceptional)
Tumors without distinct cell lineage					
Unclassified plurihormonal tumors	multiple combinations	multiple combinations	variable		variable
Null cell tumor[e]	none	none	variable		none

[a] mixed tumors also occur and can constitute any combination of tumors shown; the most common is mixed somatotroph–lactotroph tumor

[b] any tumor type can be clinically non-functioning

[c] moderate hyperprolactinaemia can occur with any sellar mass that has suprasellar extension, interrupting hypothalamic tonic dopaminergic inhibition; however, the PRL level rarely exceeds 150 ng/mL; lactotroph tumors usually show a characteristic correlation between tumor size and PRL levels, whereas other PRL-secreting tumors do not

[d] GATA2 and GATA3 are paralogues and show cross-reactivity with some available antisera

[e] null cell tumor: not synonymous with non-functioning tumor (see text for details)

Most PitNET/adenomas are sporadic,[5] and arise from a somatic mutation of single progenitor cells. However, PitNETs may also occur as part of syndromes, including:

1. multiple endocrine adenomatosis or neoplasia (MEA or MEN) (especially type I: autosomal dominant inheritance with high penetrance, also involves pancreatic islet cell tumors (which may produce gastrin and hence Zollinger-Ellison syndrome) and parathyroids (hyperparathyroidism), and in which the pituitary tumors are usually nonsecretory)
2. Carney complex (p. 652). Autosomal dominant, cardiac and cutaneous myxomas and hyperpigmentation. Associated with PitNET/adenomas that secrete either GH or GH + prolactin
3. familial isolated pituitary adenoma (FIPA). Autosomal dominant. Criteria: ≥ 2 family members with PitNET/adenomas in the absence of MEN or Carney complex. The adenomas may be of the same type (homogeneous FIPA) or of different types (heterogeneous FIPA)
4. McCune-Albright syndrome: mammosomatotroph and somatotroph tumors or hyperplasia
5. tuberous sclerosis: corticotroph tumors

51.4 Differential diagnosis of pituitary tumors

See differential diagnosis (p. 1653), which also includes non-neoplastic etiologies.

51.5 Clinical presentation of pituitary tumors

51.5.1 General information

Classically, pituitary tumors are divided into functional (or secreting), and non-functional (AKA endocrine-inactive, which are either nonsecretory or else secrete hormonally inactive products or ones that do not cause endocrinologic symptoms, e.g., gonadotropin.

Possible presentations:

1. endocrine syndromes
   a) due to hormonal excess (with *functional* tumors), (see below). Primarily, one of the following: prolactin, growth hormone, cortisol, thyroid hormone
   b) due to hormonal deficiency (p. 864) as a result of compression of the normal pituitary
2. mass effect (p. 864)
3. incidental finding on imaging done for unrelated reasons (primarily with macroadenomas) in up to 20% of the population[6]
4. pituitary apoplexy (p. 865): paroxysmal H/A with nausea and meningismus, endocrinologic and/or neurologic deficit (usually ophthalmoplegia or visual loss)
5. hydrocephalus e.g., when tumors with a large suprasellar component compresses the 3rd ventricle

Unless they are discovered on imaging performed for some other indication ("pituitary incidentaloma"[7]), functional tumors tend to present earlier as a result of symptoms caused by physiologic effects of excess hormones that they secrete[8] (this applies less to gonadotripins and to prolactinomas in males since the symptoms may be mild or unrecognized). Nonfunctional tumors usually do not present until they are large enough to cause neurologic deficits by mass effect.

51.5.2 Presentation due to hormone oversecretion (secretory tumor)

≈ 65% of adenomas secrete an active hormone (48% prolactin, 10% GH, 6% ACTH, 1% TSH)[9]:

1. prolactin (p. 867): can cause amenorrhea-galactorrhea syndrome in females, impotence in males. Etiologies:
   a) prolactinoma (p. 867): neoplasia of pituitary lactotrophs
   b) stalk effect (p. 877): pressure on the pituitary stalk may reduce the inhibitory control over prolactin secretion causing a modest increase in serum prolactin levels (PRLs)
2. growth hormone (GH): elevated GH is due to a PitNET > 95% of the time
   a) in adults: causes acromegaly (p. 870)
   b) in prepubertal children (before epiphyseal plate closure): produces pituitary gigantism (very rare)
3. corticotropin AKA adrenocorticotropic hormone (ACTH):
   a) Cushing's disease (endogenous hypercortisolism): see below
   b) Nelson syndrome (p. 869): can develop only in patients who have had an adrenalectomy
4. thyrotropin (TSH) (p. 871): secondary (central) hyperthyroidism

5. gonadotropins (follicle stimulating hormone (FSH) and less commonly luteinizing hormone (LH)): usually does not produce a clinical syndrome. Rarely produces ovarian hyperstimulation syndrome (p. 867) in women (menstrual disturbance, galacorrhea…) or testicular hypertrophy in men

51.5.3 Presentation due to mass effect

Presentation due to underproduction of pituitary hormones

May be caused by compression of the normal pituitary by large tumors. More common with nonsecretory tumors than with secretory tumors. In order of sensitivity to compression (i.e., the order in which pituitary hormones become depressed from mass effect): GH (61–100%), gonadotropins (LH & FSH) (36–96%), TSH (8–81%), ACTH (17–62%),[10] prolactin (mnemonic: **G**o **L**ook **F**or **T**he **A**denoma **P**lease). Chronic deficiency of all pituitary hormones (panhypopituitarism) may produce pituitary cachexia (AKA Simmonds' cachexia).

✖ NB: selective reduction of a single pituitary hormone is very atypical with PitNETs. May occur with autoimmune hypophysitis (p. 1656), which most commonly involves ACTH or ADH (causing diabetes insipidus[11]—see below)

Deficiency of specific hormones:

1. growth hormone deficiency (note: growth hormone stimulation test (p. 882) is more sensitive and specific for GH deficiency than measuring basal GH levels):
   a) in children: produces growth delay
   b) in adults: produces vague symptoms with metabolic syndrome (decreased lean body mass, centripetal obesity, reduced exercise tolerance, impaired sense of well-being)
   c) hypogonadism: amenorrhea (women), loss of libido, infertility
2. hypothyroidism: cold intolerance, myxedema, entrapment neuropathies (e.g., carpal tunnel syndrome), weight gain, memory disturbance, integumentary changes (dry skin, coarse hair, brittle nails), constipation, increased sleep demand
3. hypoadrenalism: orthostatic hypotension, easy fatigability
4. diabetes insipidus: almost never seen preoperatively with pituitary tumors (except possibly with pituitary apoplexy, see below). If DI is present, other etiologies should be sought, including:
   a) autoimmune hypophysitis (p. 1656)
   b) hypothalamic glioma
   c) suprasellar germ cell tumor
5. gonadotropin deficiency (hypogonadotrophic hypogonadism) with anosmia is part of Kallmann syndrome[12]

Presentation due to mass effect (other than compression of the pituitary gland)

Because they tend to get to a larger size before detection, this is more common with nonfunctioning tumors. Of functional tumors, prolactinoma is the most likely to become large enough to cause mass effect (especially in males or non-menstruating females); ACTH tumor is least likely. Nonspecific symptoms include headaches. ✖ Seizures are rarely attributable to a PitNET and other etiologies should be sought. Mass effect may occur suddenly as a result of expansion with pituitary apoplexy (see below).

Structures are commonly compressed and their manifestations include:

1. optic chiasm: from tumor growth superiorly through the diaphragma sella (▶ Fig. 52.1). Classically produces **bitemporal hemianopsia** (non-congruous) (▶ Fig. 33.2). May also cause decreasing visual acuity
2. involvement of third ventricle may produce obstructive hydrocephalus
3. cavernous sinus
   a) pressure on cranial nerves contained within (III, IV, V1, V2, VI): ptosis, facial pain, diplopia (see below)
   b) occlusion of the cavernous sinus: proptosis, chemosis
   c) encasement of the carotid artery by tumor: may cause slight narrowing, but complete occlusion is rare
4. invasive adenomas (p. 855) may present as nasal or paranasal masses
5. CSF rhinorrhea: usually with invasive adenomas often as a result of erosion of the skull base, sometimes precipitated by shrinkage of these large tumors resulting from medical treatment[13]
6. macroadenomas may produce H/A possibly via increased intrasellar pressure

51.5.4 Pituitary apoplexy

General information

Key concepts

- due to expansion of a PitNET from hemorrhage or necrosis
- typical presentation: paroxysmal H/A with nausea and meningismus, endocrinologic and/or neurologic deficit (usually ophthalmoplegia or visual field loss)
- a medical emergency due to potentially lethal adrenal insufficiency and threat of permanent visual loss
- management: immediate administration of fluids and empiric corticosteroids (hydrocortisone) for hemodynamic instability, altered mental status (GCS < 15), visual deficits (acuity or visual fields). Shunt or EVD for hydrocephalus and transsphenoidal decompression within 7 days for visual loss
- not an emergency if asymptomatic

Definition

Neurologic and/or endocrinologic deterioration due to sudden expansion of a mass within the sella turcica.

Etiology

Sudden intrasellar expansion may occur as a result of hemorrhage, necrosis,[14,15] and/or infarction within a pituitary tumor and adjacent pituitary gland. Occasionally, hemorrhage occurs into a normal pituitary gland or Rathke's cleft cyst.[16]

Epidemiology

Pituitary apoplexy (PA) occurs in an estimated 2-12% of patients with pituitary adenomas.[17] In some cases, PA may be the initial presentation of a pituitary tumor.[18] Furthermore, hemorrhage into a ptuitary tumor can be asymptomatic.

Clinical features of pituitary apoplexy

Patients often present with abrupt onset of H/A, visual disturbance, and loss of consciousness. The majority of patients present with potentially lethal adrenal insufficiency, and over 50% have visual loss and/or ophthalmoplegia.

Neurologic involvement includes:

1. visual disturbances: one of the most common findings. Includes:
    a) ophthalmoplegia (unilateral or bilateral): opposite the situation with a pituitary tumor, ophthalmoplegia occurs more often (78%) than visual pathway deficits (52–64%)[19]
    b) one of the typical field cuts (p. 875) seen in pituitary tumors
2. acute secondary adrenal insufficiency (hypocortisolism) occurs in 66% and is the major source of mortality
    a) fluid and electrolyte disturbances may be caused by vasopressin release from the posterior pituitary
    b) hemodynamic instability may result from reduced vascular response to catecholamines caused by hypocortisolism
3. reduced mental status (lethargy, stupor, or coma): due to ↑ ICP (from intracranial extension of blood or to hydrocephalus) or hypothalamic involvement
4. cavernous sinus compression can cause venous stasis and/or pressure on any of the structures within the cavernous sinus
    a) trigeminal nerve symptoms
    b) proptosis
    c) ophthalmoplegia (Cr. N. III palsy is more common than VI) in 70% of cases[20]
    d) ptosis may be an early symptom[21,22]

   e) pressure on carotid artery
   f) compression of sympathetics within the cavernous sinus may produce third order (incomplete) Horner syndrome with unilateral ptosis and miosis, but anhidrosis may be absent or limited to the central forehead[23]
   g) carotid artery compression may cause stroke or vasospasm
5. when hemorrhage breaks through the tumor capsule and the arachnoid membrane into the chiasmatic cistern, signs and symptoms of SAH may be seen
   a) N/V
   b) meningismus
   c) photophobia
6. hypothalamic involvement may produce
   a) hypotension
   b) thermal dysautoregulation
   c) cardiac dysrhythmias
   d) respiratory pattern disturbances
   e) diabetes insipidus
   f) altered mental status: lethargy, stupor, or coma
7. suprasellar expansion can produce acute hydrocephalus

Evaluation

In cases due to hemorrhage: CT or MRI shows hemorrhagic mass in sella turcica and/or suprasellar region, often distorting the anterior third ventricle.

Cerebral angiography or CTA should be considered in cases where differentiating pituitary apoplexy from aneurysmal SAH is difficult.

Management of pituitary apoplexy

Rapid empiric administration of corticosteroids is indicated for hemodynamic instabilty, altered mental status (GCS < 15), or visual deficits (acutiy or field cuts).[20] Typical dose: hydrocortisone 100-200 mg IV bolus followed by 2-4 mg/hr IV infusion.[20] ✖ Dexamethasone alone is not recommended as it is deficient in the necessary mineralocorticoid activity. Patients without the aforementioned emergency findings may be evaluated endocrinologically and have corticosteroid replacement if deficient.

In the absence of visual deficits, prolactinomas may be treated with dopamine agonists (bromocriptine, cabergoline…).

Rapid decompression is required for: sudden constriction of visual fields, severe and/or rapid deterioration of visual acuity, or neurologic deterioration due to hydrocephalus. Surgery in ≤ 7 days of pituitary apoplexy resulted in better improvement in ophthalmoplegia (100%), visual acuity (88%), and field cuts (95%) than surgery after 7 days, based on a retrospective study of 37 patients.[24] Decompression is usually via a transsphenoidal route (transcranial approach may be advantageous in some cases). Goals of surgery:
1. to decompress the following structures if under pressure: optic apparatus, pituitary gland, cavernous sinus, third ventricle (relieving hydrocephalus)
2. obtain tissue for pathology
3. complete removal of tumor is usually not necessary
4. for hydrocephalus: ventricular drainage is generally required

51.6 Specific types of pituitary tumors

51.6.1 Nonfunctioning PitNET/adenomas (NFPA)

Nonfunctioning PitNET/adenoma (NFPA) is a clinical definition, viz. a pituitary adenoma that does not produce signs or symptoms as a result of hormonal hypersecretion.[25] NFPAs are the most common pituitary tumors,[4] comprising 15–30% of PitNETs.[26] They are predominantly derived from gonadotroph cells[25] and most actually do secrete gonadotropins or gonadotropin subunits,[27] but this is rarely symptomatic (see below). Most are either found incidentally or present due to signs and/or symptoms due to mass effect (p. 864). For management see section 53.1.3.

51.6.2 Gonadotropin (FSH, LH) secreting tumors

As indicated above, most of these tumors do not produce clinical symptoms and are therefore considered nonfunctioning adenomas (80–90% of “nonfunctioning adenomas” are gonadotroph adenomas[28]). Rarely, clinical findings may occur:

- FSH: may cause **ovarian hyperstimulation syndrome** in reproductive-age women causing menstrual irregularities (including amenhrrhea) and glactorrhea (as with prolactin) along with ovarian cysts,[25,29] and rarely testicular hypertrophy and sexual dysfunction in men
- LH: even more rare, reported as causing precocious puberty in 2 boys[25]

51.6.3 Prolactinomas (lactotroph tumor)

The most common secretory adenoma. Arise from neoplastic transformation of anterior pituitary lactotrophs. See ▶ Table 52.4 for the differential diagnosis of hyperprolactinemia.

Manifestations of prolonged hyperprolactinemia:

1. females: amenorrhea-galactorrhea syndrome (AKA Forbes-Albright syndrome, AKA Ahumada-del Castillo syndrome). Variants: oligomenorrhea, irregular menstrual cycles. 5% of women with primary amenorrhea will be found to have a prolactin-secreting pituitary tumor.[30] Remember: pregnancy is the most common cause of secondary amenorrhea in females of reproductive potential. The galactorrhea may be spontaneous or expressive (only on squeezing the nipples)
2. males: impotence, decreased libido. Galactorrhea is rare (estrogen is also usually required). Gynecomastia is rare. Prepubertal prolactinomas may result in small testicles and feminine body habitus
3. either sex:
    a) infertility is common
    b) bone loss (osteoporosis in women, and both cortical and trabecular osteopenia in men) due to a relative estrogen deficiency, not due to the elevated prolactin itself

At the time of diagnosis, 90% of prolactinomas in women are microadenomas, vs. 60% for males (probably due to gender-specific differences in symptoms resulting in earlier presentation in females). Some tumors secrete both prolactin and GH.

51.6.4 Cushing’s disease

General information and Cushing’s syndrome

Cushing’s syndrome (CS) is a constellation of findings caused by hypercortisolism. Cushing’s disease (p. 867)—endogenous hypercortisolism due to hypersecretion of ACTH by an ACTH-secreting PitNET—is just one cause of CS. The most common cause of CS is iatrogenic (administration of exogenous steroids). Possible etiologies of *endogenous* hypercortisolism are shown in ▶ Table 51.2. To determine the etiology of CS, see Dexamethasone suppression test (p. 879).

Table 51.2 Causes of endogenous hypercortisolism

Site of pathology	Secretion product	Percent of cases	ACTH levels
pituitary corticotroph adenoma: Cushing’s disease (p. 867)	ACTH	60–80%	slightly elevated[a]
ectopic ACTH production (p. 868); most are lung tumors, others: pancreas…		1–10%	very elevated
adrenal (adenoma or carcinoma)	cortisol	10–20%	low
hypothalamic or ectopic secretion of corticotropin-releasing hormone (CRH) producing hyperplasia of pituitary corticotrophs; pseudo-Cushing’s state (p. 868)	CRH	rare	elevated

[a] ACTH may be normal or slightly elevated; normal ACTH levels in the presence of hypercortisolism are considered inappropriately elevated

Conversion factors[31] for ACTH and cortisol between U.S. units and SI units are shown in Eq (51.1) and (51.2).

$$\text{ACTH}: 1\text{pg}/\text{ml} = 1\text{ng}/\text{liter} \tag{51.1}$$

$$\text{Cortisol}: 1\mu\text{g}/\text{dl} = 27.59\ \text{nmol}/\text{liter} \tag{51.2}$$

Ectopic ACTH secretion

Hypercortisolism may also be due to ectopic secretion of ACTH usually by tumors, most commonly small-cell carcinoma of the lung, thymoma, carcinoid tumors, pheochromocytomas, and medullary thyroid carcinoma. In addition to findings of Cushing’s syndrome, patients are typically cachectic due to the malignancy which is usually rapidly fatal.

Prevalence of Cushing’s disease

40 cases/million population. ACTH-producing adenomas comprise 10–12% of pituitary adenomas.[32] Cushing’s disease is 9 times more common in women, whereas *ectopic* ACTH production is 10 times more common in males. Non-iatrogenic CS is 25% as common as acromegaly.

At the time of presentation, over 50% of patients with Cushing’s disease have pituitary tumors < 5 mm in diameter, which are very difficult to image with CT or MRI. Most are basophilic, some (especially the larger ones) may be chromophobic. Only ≈ 10% are large enough to produce some mass effect, which may cause enlargement of the sella turcica, visual field deficit, cranial nerve involvement, and/or hypopituitarism.

Clinical findings in Cushing’s disease

Findings are those of Cushing’s syndrome (hypercortisolism from any cause) include:

1. weight gain
   a) generalized in 50% of cases
   b) centripetal fat deposition in 50%: trunk, upper thoracic spine (“buffalo hump”), supraclavicular fat pad, neck, “dewlap tumor” (episternal fat), with round plethoric face (“moon facies” AKA “Cushingoid facies”) and slender extremities
2. hypertension
3. ecchymoses and purple striae, especially on flanks, breasts, and lower abdomen
4. amenorrhea in women, impotence in men, reduced libido in both
5. hyperpigmentation of skin and mucous membranes: due to MSH cross-reactivity of ACTH. Occurs only with elevated ACTH, i.e., Cushing’s disease (not Cushing’s syndrome) or ectopic ACTH production (also below)
6. atrophic, tissue-paper thin skin with easy bruising and poor wound healing
7. psychiatric: depression, emotional lability, dementia
8. osteoporosis
9. generalized muscle wasting with complaints of easy fatigability
10. elevation of other adrenal hormones: androgens may produce hirsutism and acne
11. sepsis: associated with advanced Cushing’s syndrome

Laboratory findings in Cushing’s disease

1. hyperglycemia: diabetes or glucose intolerance
2. hypokalemic alkalosis
3. loss of diurnal variation in cortisol levels
4. normal or elevated ACTH levels
5. failure to suppress cortisol with low-dose (1 mg) dexamethasone test (p. 879)
6. elevated 24-hour urine-free cortisol

7. CRH levels will be low (not commonly measured)

Nelson's syndrome (or Nelson syndrome) (NS)

General information

Key concepts

- a rare condition that follows 10–30% of total bilateral adrenalectomies (TBA) performed for Cushing's disease; see indications for TBA (p. 892)
- classic triad: hyperpigmentation (skin & mucus membranes), abnormal ↑ ACTH, and progression of pituitary tumor (the last criteria is now controversial)
- treatment options: surgery (transsphenoidal or transcranial), XRT, medication

A rare condition that follows 10–30% of total bilateral adrenalectomies (TBA) performed for Cushing's disease; see indications for TBA (p. 891). NS is due to continued growth of corticotroph (ACTH-secreting) adenoma cells. Usually occurs 1–4 years after TBA (range: 2 mos-24 years).[32] Theoretical explanation (unproven)[33]: following TBA, hypercortisolism resolves, and CRH levels increase back to normal from the (reduced) suppressed state; corticotroph adenomas in patients with NS have an increased & prolonged response to CRH resulting in increased growth. Also, corticotrophs in NS and CD show reduced inhibition by glucocorticoids. It is controversial if some cases may be related to insufficient glucocorticoid replacement after TBA.[32]

Manifestations

See reference.[33]

1. hyperpigmentation (due to melanin stimulating hormone (MSH) cross reactivity of ACTH and actual increased levels of MSH due to increased proopiomelanocortin production). Often the earliest sign that Nelson's syndrome is developing. Look for linea nigra (midline pigmentation from pubis to umbilicus) and hyperpigmentation of scars, gingivae, and areolae. DDx of hyperpigmentation includes: primary adrenal insufficiency (high levels of ACTH), ectopic ACTH secretion, hemochromatosis (more bronze color), jaundice (yellowish)
2. tumor growth → increased mass effect (p. 864) or invasion: the most serious consequence. These corticotroph tumors are among the most aggressive of pituitary tumors.[34(p 545)] May produce any of the problems associated with macroadenomas (optic nerve compression, cavernous sinus invasion, pituitary insufficiency, H/A, bony invasion…) as well as necrosis with precipitous intracranial hypertension[35]; see pituitary apoplexy (p. 865)
3. malignant transformation of the corticotroph tumor (very rare)
4. hypertrophy of adrenal tissue rests: may be located in the testes → painful testicular enlargement and oligospermia. Rarely the rests can secrete enough cortisol to normalize cortisol levels or even cause a recurrence of Cushing's disease despite the adrenalectomy

Evaluation

1. laboratories
   a) ACTH > 200 ng/L (usually thousands of ng/L) (normal: usually < 54 ng/L)
   b) exaggerated ACTH response to CRH (not required for diagnosis)
   c) other pituitary hormones may be affected as with any macroadenoma-causing mass effect (p. 864) and endocrine screening (▶ Table 52.1) should be done
2. formal visual field testing (p. 874): should be done in patients with suprasellar extension or in those being considered for surgery (as a baseline for comparison)

Treatment

See treatment (p. 888).

51.6.5 Acromegaly

General information

Key concepts

- abnormally high levels of growth hormone in an adult. > 95% of cases are due to a benign pituitary somatotroph adenoma, > 75% are > 10 mm at time of diagnosis
- effects include soft tissue and skeletal changes, cardiomyopathy, colon Ca
- work-up: endocrine tests (p. 874), cardiology consult, colonoscopy
- treatment (p. 889): surgery for most, and then if necessary, medical therapy (p. 889) and/or XRT (p. 893)
- suggested criteria for biochemical cure (p. 903): normal IGF-1, growth hormone level < 5 ng/ml, AND GH nadir of < 1 ng/ml after OGST (p. 882)

Incidence: 3 cases/1-million persons/year. > 95% of cases of excess GH result from a pituitary somatotroph adenoma. Ectopic GH secretion may occur uncommonly with: carcinoid tumor, lymphoma, pancreatic islet-cell tumor. By the time of diagnosis, > 75% of pituitary GH tumors are macroadenomas (> 10 mm dia) with cavernous sinus invasion and/or suprasellar extension.

25% of acromegalics have thyromegaly with normal thyroid studies. 25% of GH adenomas also secrete prolactin. Acromegaly occurs rarely as part of a genetic syndrome, including: multiple endocrine neoplasia type 1 (MEN 1), McCune-Albright syndrome (p. 975), familial acromegaly, and Carney complex (p. 652).[36]

Clinical

Elevated levels of GH in children before closure of the epiphyseal plates in the long bones (shortly after puberty) produces gigantism. Usually presents in the teen years. Hypertension may also occur.

In adults, elevated GH levels produce acromegaly (age: usually > 50 yrs) with findings that may include[37,38] (also see ▶ Table 51.3):

1. skeletal overgrowth deformities
   a) increasing hand and foot size
   b) thickened heel pad
   c) frontal bossing
   d) prognathism
2. cardiovascular
   a) cardiac findings (structural and functional): arrhythmias, valvular disease, concentric myocardial hypertrophy
   b) hypertension (30%)
3. soft tissue swelling (includes macroglossia)
4. glucose intolerance
5. peripheral nerve entrapment syndromes (including carpal tunnel syndrome)
6. debilitating headache
7. excessive perspiration (especially palmar hyperhidrosis)
8. oily skin
9. joint pain
10. sleep apnea
11. fatigue
12. colon cancer: risk is ≈ 2 × risk of general population[39]

Patients with elevated levels of GH (including partially treated cases) have 2–3 times the expected mortality rate,[40] primarily due to hypertension, diabetes, pulmonary infections, cancer, and cardiovascular disease (▶ Table 51.3). Soft-tissue swelling and nerve entrapment may be reversible with normalization of GH levels, but many disfiguring changes and health risks are permanent (see ▶ Table 51.3 for specifics).

Table 51.3 Risks of long-term exposure to excess growth hormone (GH)[40]

Arthropathy
1. unrelated to age of onset or GH levels 2. usually with longstanding acromegaly 3. reversibility[a]: a) rapid symptomatic improvement b) bone & cartilage lesions irreversible
Peripheral neuropathy
1. intermittent anesthesias, paresthesias 2. sensorimotor polyneuropathy 3. impaired sensation 4. reversibility[a]: a) symptoms may improve b) onion bulbs (whorls) do not regress
Cardiovascular disease
1. cardiomyopathy a) reduced LV diastolic function b) increased LV mass and arrhythmias c) fibrous hyperplasia of connective tissue 2. HTN: exacerbates cardiomyopathic changes 3. reversibility[a]: may progress even with normal GH
Respiratory disease
1. upper airway obstruction: caused by soft tissue overgrowth and decreased pharyngeal muscle tone with sleep apnea in ≈ 50% 2. reversibility[a]: generally improves
Neoplasia
1. increased risk of malignancies (especially colon-Ca) & soft-tissue polyps 2. reversibility[a]: unknown
Glucose intolerance
1. occurs in 25% of acromegalics (more common with family history of DM) 2. reversibility[a]: improves

[a]reversibility with normalization of GH levels

51.6.6 Thyrotropin (TSH)-secreting adenomas (thyrotroph adenoma)

General information

Rare: comprise ≈ 0.5–1% of pituitary tumors.[9,41] Produces central (secondary) hyperthyroidism (note: central hyperthyroidism may also occur with pituitary resistance to thyroid hormones[42]): elevated circulating T3 and T4 levels, with elevated or inappropriately normal TSH[42] (TSH should be undetectable in primary hyperthyroidism). Up to 33% of tumors positive for TSH immunostaining are nonsecretory.[42] Many of these tumors are plurihormonal, but the secondary hormone is usually clinically silent. Most of these tumors are aggressive and invasive and are large enough at presentation to also produce mass effect (especially if prior thyroid ablative procedures have been done, which occurs in up to 60% of cases due to lack of recognition of pituitary abnormality.[42,43])

Clinical

Symptoms of hyperthyroidism: anxiety, palpitations (due to a-fib), heat intolerance, hyperhidrosis, and weight loss despite normal or increased intake. Signs: hyperactivity, lid lag, tachycardia, irregular rhythm when a-fib is present, hyperreflexia, tremor. Exophthalmos and infiltrative dermopathy (e.g., pretibial myxedema) are present only in Graves' disease.

51.6.7 Pathological classification of pituitary tumors

Light microscopic appearance of adenomas

Obsolete classification system (presented for completeness). With newer techniques (EM, molecular biology, immunohistochemistry…), many tumors previously considered nonsecretory have been found to have all the components necessary to secrete hormones.

In order of decreasing frequency:

1. chromophobe: most common (ratio of chromophobe to acidophil is 4-20:1). Originally considered “non-secretory,” in actuality may produce prolactin, GH, or TSH
2. acidophil (eosinophilic): produce prolactin, TSH, or usually *GH*
3. basophil→ gonadotropins, β-lipotropin, or usually *ACTH* → *Cushing’s disease*

Classification of adenomas based on secretory products

1. endocrine-active tumors: ≈ 70% of pituitary tumors produce 1 or 2 hormones that are measurable in the serum and cause defined clinical syndromes; these are classified based on their secretory product(s)
2. endocrine-inactive (nonfunctional) tumors[44] (**note:** a and b constitute the bulk of endocrine-inactive adenomas):
   a) oncocytoma
   b) gonadotropin-secreting adenoma
   c) silent corticotropin-secreting adenoma
   d) glycoprotein-secreting adenoma

Tumors of the neurohypophysis and infundibulum

The most common tumors encountered in the posterior pituitary are metastases (owing to the rich blood supply and the rarity of posterior pituitary tumors).

See Tumors of the neurohypophysis and infundibulum (p. 852) for details of specific tumor types (granular cell tumor, pituicytoma, and spindle cell oncocytoma).

52 Pituitary Tumors – Evaluation

52.1 History and physical

Directed to identify signs and symptoms of:

1. endocrine hyperfunction, including:
    a) prolactin: amenorrhea (women), nipple discharge (primarily in women since estrogen is also required), impotence (males)
    b) thyroid: heat intolerance, proptosis
    c) growth hormone. Adults: change in ring size or shoe size or coarsening of facial features (acromegaly). Children: gigantism
    d) cortisol: hyperpigmentation, Cushingoid features (moon facies, buffalo hump…)
2. endocrine deficits due to mass effect (p. 864) on pituitary: hypothyroidism, hypocortisolism, growth hormone deficit…
3. visual field deficit: classically bitemporal hemianopsia (▶ Fig. 33.2) due to compression of the optic chiasm. Use bedside confrontational testing (p. 588) as a screening test until formal visual fields can be obtained
4. deficits of cranial nerves within cavernous sinus
    a) III, IV, VI: disorder of pupil and extraocular muscles
    b) V1, V2: reduced sensation in forehead, nose, upper lip, and cheek

52.2 Diagnostic tests

52.2.1 Overview

Initial (screening) tests to work-up a patient presenting with a known or suspected pituitary mass are shown in ▶ Table 52.1. Further testing is indicated for abnormal results or for strong suspicion of specific syndromes.

52.2.2 Vision evaluation

General information

Practice guideline: Visual evaluation with PitNET/adenomas*

Level III[2]

- evaluation by an ophthalmologist is recommended
- automatic static perimetry is recommended to detect visual field defects
- visual evoked potentials may be useful in certain situations (e.g., when acuity and visual fields cannot be assessed) but the usefulness for routine testing is limited by significant false negative and false positive results
- older patients and those with visual loss > 4 months should be advised that the chances of return of vision post-op are reduced
- optical coherence tomography (OCT): not a practice standard. May be used to document extent of damage to optic disc

* these guidelines were developed for suspected *nonfunctioning* PitNET/adenomas, principles may not be generalizable

At a minimum, formal visual field testing should be done in all patients to detect visual field deficits and to serve as a baseline.

Visual fields

Formal visual field testing:

- by perimetry using a tangent screen (Goldmann perimetry). Use the small red stimulus since desaturation of color is an early sign of chiasmal compression
- or automated perimetry (p. 589) (recommended[2]). E.g., Humphrey perimeter

Table 52.1 Summary of initial (screening) work-up for pituitary tumors (see indicated page for details)

Evaluation	Rationale
Vision to detect visual field deficits and serve as a baseline	
✓ Formal visual fields (most commonly Humphrey automated visual fields (HVF))	• compression of optic chiasm → visual field deficit (classically bitemporal hemianopsia, ▶ Fig. 33.2)
Endocrine screening	
✓ 8 A.M. cortisol[a] and/or 24-hour urine free cortisol[a]	• cortisol ↓ in hypoadrenalism (primary or secondary) • cortisol ↑ in hypercortisolism (Cushing syndrome) (p. 876)
✓ TSH & either free T4 or free T4 index (FTI)[b] (✖ total T4 is not recommended for this purpose[b])	**Hypothyroidism** • T4 ↓ & TSH ↑ in primary hypothyroidism (this may cause thyrotroph hyperplasia in the pituitary gland) • T4 ↓ & TSH nl or ↓ in secondary hypothyroidism (as in hypopituitarism)
	Hyperthyroidism (thyrotoxicosis) • T4 ↑ & TSH ↓ in primary hyperthyroidism • T4 ↑ & TSH ↑ in TSH-secreting PitNETs
✓ prolactin	• ↑ or ↑↑ with prolactinoma
	• slight ↑ with stalk effect (usually < 90 ng/ml)
✓ gonadotropins (FSH, LH) and sex steroids[c] (♀: estradiol, ♂: testosterone)	• ↓ in hypogonadotrophic hypogonadism (from mass effect causing compression of the pituitary gland) • ↑ with gonadotropin-secreting adenoma
✓ insulin-like growth factor-1 (IGF-1) AKA somatomedin-C[d]	• ↑ in acromegaly • ↓ in hypopituitarism (one of the most sensitive markers)
✓ fasting blood glucose	• ↓ in hypoadrenalism (primary or secondary) • ↑ with hyperadrenalism
Radiographic studies (p. 882) ✓ either:	
• MRI without & with contrast brain & pituitary protocol (test of choice), include image navigation protocol if navigation is to be used. Some surgeons also get noncontrast brain CT to delineate bony anatomy (especially of sphenoid sinus) • if MRI is contraindicated: CT without & with contrast (with coronal reconstruction) + cerebral angiogram	

[a] 8 A.M. cortisol is the best test for hypocortisolism (e.g., to look for pituitary insufficiency); 24-hour urine free-cortisol is the best test for hypercortisolism (p. 876) [1] (e.g., to look for Cushing's syndrome)

[b] free T4 and TFI measure thyroid hormone available to tissues ("ignoring" protein bound hormone)

[c] elevated estrogen or testosterone from a pituitary tumor is extremely rare, and is usually related to exogenous hormone intake or dietary supplements (such as dehydroepiandrosterone (DHEA))

[d] IGF-1 is the primary test for excess growth hormone (GH); direct measurement of GH is unreliable due to pulsatile secretion

▶ **Visual field deficit patterns** (▶ **Fig. 33.2**). Depends in part on location of chiasm with respect to the sella turcica: the chiasm is located above the sella in most patients, but it is posterior to the sella turcica (postfixed chiasm) in 4% (on imaging); and anterior to the sella (pre-fixed chiasm) in 8%[3]

1. compression of the optic chiasm:
   a) bitemporal hemianopsia that obeys the vertical meridian (macular splitting): classic visual field deficit associated with a pituitary tumor. Due to impingement on crossing nasal fibers in the chiasm
   b) other reported patterns that occur rarely: monocular temporal hemianopsia
2. optic nerve compression: more likely in patients with a postfixed chiasm
   a) loss of vision in the ipsilateral eye. If carefully sought, there is usually a superior outer (temporal) quadrantanopsia in the contralateral eye[4 (p 2135),5] ("pie in the sky" defect*) from compression of the anterior knee of Wilbrand (p. 1478); may also be an early finding even without a post-fixed chiasm (so-called junctional scotoma = monocular visual loss + superior temporal quadrantanopsia in the contralateral eye)
      * this "pie in the sky" defect is in the contralateral eye only, unlike the defect with Meyer's loop injuries which is bilateral
   b) may produce central scotoma or monocular reduction in visual acuity
3. compression of the optic tract: may occur with a pre-fixed chiasm. Produces homonymous hemianopsia

Ophthalmology consult

A recommended option, see Practice guideline: Visual evaluation with PitNET/adenomas (p. 874). In addition to visual field testing, it provides evaluation of the optic disc and other visual deficits and may help provide prognostic information for any visual loss that may be present.

Ancillary visual testing

Visual evoked potentials: usefulness is limited, see Practice guideline: Visual evaluation with pituitary adenomas (p. 874).

Optical coherence tomography (OCT): an option, see Practice guideline: Visual evaluation with PitNET/adenomas (p. 874) Uses light waves to provide high-resolution information about the thickness of the retina (including the optic disc). Does not utilize ionizing radiation. May be able to provide prognostic information.[6]

52.2.3 Initial endocrinologic evaluation (screening)

Overview

Practice guideline: Endocrine evaluation of PitNET/adenomas*

- Level II[7]:
  - all anterior pituitary axes should be routinely evaluated
  - prolactin levels should be routinely tested
  - cutoff values to initiate thyroid and adrenal replacement may be different in patients with panhypopituitarism (as opposed to patients with isolated deficits)
  - adrenal insufficiency and significant hypothyroidism should be treated pre-op
- Level III[7]: IGF-1 should be routinely tested to rule out subclinical growth hormone hypersecretion

* these guidelines were developed for suspected *nonfunctioning* PitNET/adenomas, principles may not be generalizable

See ▶ Table 52.1. May give indication of tumor type, determines whether any hormones need to be replaced, and serves as a baseline for comparison following treatment. Includes clinical assessment for signs and symptoms, as well as laboratory tests. Screening tests for anterior pituitary hormones should be checked in all patients with pituitary tumors.[7] Note: selective loss of a *single* pituitary hormone together with thickening of the pituitary stalk is strongly suggestive of autoimmune hypophysitis (p. 1656).

1. adrenal axis screening; see tests to assess **cortisol reserve** (p. 880)
   a) cortisol levels generally peak between 7–8 AM. AM cortisol may normally be slightly elevated above the reference range. 8 AM cortisol level: better for detecting hypocortisolism.[1] Normal: 6–18 mcg/100 ml. Interpretation:
      - 8 AM cortisol < 6 mcg/100 ml: suggestive of adrenal insufficiency
      - 8 AM cortisol 6–14 mcg/100 ml: nondiagnostic
      - 8 AM cortisol > 14 mcg/100 ml: adrenal insufficiency is unlikely

   b) see distinguishing Cushing's disease from ectopic ACTH secretion (p. 880) in questionable cases, including differentiating pseudo-Cushing states from Cushing's syndrome
   c) 24-hour urine free cortisol: more accurate for ***hypercortisolism***[1] (almost 100% sensitive and specific, false negative rare except in stress or chronic alcoholism). If not elevated several times above normal, at least 2 additional determinations should be made[8]
2. thyroid axis: the basis for thyroid screening is shown in ▶ Table 52.2
   a) screening: T4 level (total or free), thyroid-stimulating hormone (TSH) (AKA thyrotropin). Normal values: free T4 index is 0.8–1.5, TSH 0.4–5.5 mcU/ml, total T4 4–12 mcg/100 ml (NB: be sure to check both T4 *AND* TSH)
   b) further testing: thyrotropin-releasing hormone ***(TRH) stimulation test*** (indicated if T4 is low or borderline): check baseline TSH, give 500 mcg TRH IV, check TSH at 30 & 60 mins. Normal response: peak TSH twice baseline value at 30 mins. Impaired response with a low T4 indicates pituitary deficiency. Exaggerated response suggests primary hypothyroidism

3. gonadal axis
   a) screening:
      - serum gonadotropins: FSH & LH
      - sex steroids: estradiol in women, testosterone in men (measure *total* testosterone)

   b) further testing: none dependable in differentiating pituitary from hypothalamic disorders
4. prolactin levels (PRLs): for prolactin neurophysiology (p. 151)
   a) interpretation is shown in ▶ Table 52.3. See ▶ Table 52.4 for differential diagnosis of hyperprolactinemia. With prolactinomas, PRL correlates with size of the tumor[9]: if PRL is < 200 ng/ml, ≈ 80% of tumors are microadenomas, and 76% of these will have normal PRL after surgery; if PRL > 200, only ≈ 20% are microadenomas

   b) blood samples should be obtained midmorning (i.e., not soon after awakening) and not after stress, breast stimulation, or physical examination, which may increase PRLs

   c) be aware of the following when interpreting PRLs:
      - because of variations in secretion (daily PRL fluctuations can be as high as 30%) and intrinsic inaccuracies of radioimmunoassay, PRLs should be rechecked if there is a reason to question a specific result
      - heterophilic antibodies (seen in individuals routinely exposed to animal serum products) can cause anomalous results
      - **stalk effect**: prolactin is the only pituitary hormone primarily under inhibitory regulation (p. 153). Injury to or compression of the hypothalamus or pituitary stalk from surgery or compression by any type of tumor can cause modest elevation of PRL due to decrease in prolactin inhibitory factors (PIFs). Rule of thumb: the percent chance of an elevated PRL being due to a prolactinoma is ≈ one half the PRL (details (p. 878))
      - lab report stating "prolactin level > X": if the lab reports the PRL as " > X" (where X is some high value, e.g., 500 ng/ml) instead of specifying an actual number, it usually indicates a PRL so high that it exceeds the upper limits of the assay. Determining the actual number usually requires performing serial dilutions on the specimen until the PRL is in a range that their assay can quantify. Some labs will do this reflexively. If not, contact the lab and ask them to do this (they may be able to be done with the specimen they have, or else the patient will need to have another blood draw). This is important for:
        treatment decisions: **PRL > 500** usually indicates that surgery alone will not be able to normalize the PRL (see management guidelines (p. 888));
        to assess response to treatment: it is essential to know what PRL you are starting with to determine response to medication, surgery, XRT…
      - hook effect: extremely high PRLs may overwhelm the assay (the large numbers of PRL molecules prevent the formation of the necessary PRL-antibody-signal complexes for radioimmunoassay) and produce falsely low results. Therefore, for large adenomas with a normal PRL and a high clinical suspicion of hyperprolactinemia, have the lab perform several dilutions of the serum sample and re-run the PRL
      - macroprolactinemia: occurs when prolactin molecules polymerize and bind to immunoglobulins. Prolactin in this form has reduced biological activity but produces lab values consistent with hyperprolactinemia. Clinical significance is controversial[10]; asymptomatic patients usually do not require treatment
5. growth hormone: due to pulsatile secretion of GH:
   a) IGF-1 (somatomedin-C) level (p. 881) is the recommended initial test (elevated IGF-1 is extremely sensitive for acromegaly)

   b) checking a single random GH level (p. 881) may not be a reliable indicator and is therefore *not* recommended
6. neurohypophysis (posterior pituitary): deficits are rare with pituitary tumors
   a) screening: check adequacy of ADH by demonstrating concentration of urine with water deprivation

   b) further testing: measurement of serum ADH in response to infusion of hypertonic saline

Thyroid screening

Table 52.2 Basis for thyroid screening (T4 snd TSH)

Rationale	T_4	TSH
Primary hypothyroidism[a] (problem with thyroid gland itself)	↓	↑
• chronic primary hypothyroidism may produce secondary pituitary hyperplasia (pituitary pseudotumor) indistinguishable from adenoma on CT or MRI. Must be considered in any patient with a pituitary mass[11,12] • pathophysiology: loss of negative feedback from thyroid hormones causes increased TRH release from the hypothalamus producing secondary hyperplasia of thyrotrophic cells in the adenohypophysis (thyrotroph hyperplasia). The patient may present due to pituitary enlargement (visual symptoms, elevated PRL from stalk effect, enlarged sella turcica on X-rays...) • chronic stimulation from elevated TRH may rarely produce thyrotroph adenomas • labs: T_4 low or normal, TSH elevated (> 90–100 in patients presenting with thyrotroph hyperplasia), prolonged and elevated TSH response to TRH stimulation test (see text)		
Secondary hypothyroidism[a] (insufficient TSH stimulation of thyroid)	↓	**↓ or nl**
• pituitary hypothyroidism accounts for only ≈ 2–4% of all hypothyroid cases[13] • secondary hypothyroidism was found in 8–81% of patients with nonfunctioning pituitary tumors[7] (pituitary compression reduces TSH) • labs: T_4 low, TSH low or normal, reduced response to TRH stimulation test (see text)		
Primary hyperthyroidism (problem with thyroid gland itself)	↑	↓
• etiologies: localized hyperactive thyroid nodule, circulating antibody that stimulates the thyroid, or diffuse thyroid hyperplasia (Graves' disease, AKA ophthalmic hyperthyroidism) • labs: T_4 elevated, TSH subnormal (usually *undetectable*)		
Secondary hyperthyroidism (central hyperthyroidism)	↑	**↑ or nl**

• etiologies
  ○ TSH-secreting PitNET/adenoma (rare)
  ○ pituitary resistance to thyroid hormones (disrupts negative feedback loop)
• labs: T_4 elevated, TSH elevated or inappropriately normal		

[a] ✖ Caution: replacing thyroid hormone with inadequate cortisol reserves (as may occur in panhypopituitarism) can precipitate adrenal crisis; see management (p. 886)

Prolactin screening

Interpretation of prolactin levels (PRL) is shown in ▶ Table 52.3.

Table 52.3 Significance of prolactin levels[a]

PRL (ng/ml)	Interpretation	Situations observed in
3–30[b]	normal	non-pregnant female
10–400		pregnancy (▶ Table 52.4)
2–20		postmenopausal female
25[b]-150	moderate elevation	• prolactinoma • "stalk effect" (see text) • other causes[d]
> 150[c]	significant elevation	prolactinoma[d]

[a] note: ectopic sites of prolactin secretion have rarely been reported (e.g., in a teratoma[14])
[b] normal values vary, use your lab's reference range
[c] some authors recommend 200 ng/ml as the cutoff for probable prolactinomas[15]
[d] for DDx of hyperprolactinemia, see ▶ Table 52.4

For differential diagnosis of hyperprolactinemia, see ▶ Table 52.4.

▶ **Stalk effect.** Modest elevation of prolactin level (PRL) tue to loss of inhibitory effect of PRIF from hypothalamus. There is no Class I evidence to support a threshhold to distinguish between stalk effect and a prolactinoma.[7] Mean PRL in nonfunctioning PitNETs was 39 ng/ml, with a majority of patients with stalk effect having PRL < 200 ng/ml.[7] Rule of thumb: the percent chance of an elevated

Table 52.4 Differential diagnosis of elevated prolactin (PRL) level (hyperprolactinemia)[a]

1. pregnancy-related
    a) during pregnancy[b]: 10–400 ng/ml
    b) postpartum: PRL decreases ≈ 50% (to ≈ 100 ng/ml) in the first week postpartum, and is usually back to normal in 3 weeks
    c) in the lactating female: suckling increases prolactin, which is critical for lactogenesis (once initiated, nonpregnant PRLs can maintain lactation).
    First 2–3 months postpartum: basal PRL = 40–50 ng/ml, suckling → increases × 10–20. 3–6 months postpartum: basal PRLs become normal or slightly elevated, and double with suckling. PRL should normalize by 6 months after weaning
2. PitNET/adenoma
    a) prolactinoma: larger prolactin microadenomas and macroadenomas usually produce PRL > 100 ng/ml
    b) stalk effect (p. 877): rule of thumb, the percent chance of an elevated PRL being due to a prolactinoma is equal to one half the PRL
    c) some tumors secrete both PRL and GH
3. drugs: dopamine receptor antagonists (e.g., phenothiazines, metoclopramide), oral contraceptives (estrogens), tricyclic antidepressants, verapamil, H2 antagonists (e.g., ranitidine), some SSRIs, in particular paroxetine (Paxil®)[16], carbamezepine rarely produces clinically significant increases[17]…
4. primary hypothyroidism: TRH, a prolactin releasing factor (PRF) (p. 153), will be elevated
5. empty sella syndrome (p. 955)
6. transient elevations in human serum prolactin (HSP) levels occur following 80% of generalized motor, 45% of complex partial, and only 15% of simple partial seizures.[18] Peak levels are reached in 15–20 minutes, and gradually return to baseline over the subsequent hour.[19,20,21]
7. breast or chest-wall trauma/surgery: usually ≤ 50 ng/ml
8. excessive exercise: usually ≤ 50 ng/ml
9. stress: in some cases the stress of having the blood test is enough to elevate PRL, anorexia nervosa
10. ectopic secretion: reported in renal cell or hepatocellular tumors, uterine fibroids, lymphomas
11. infiltrating hypothalamic tumors
12. renal failure
13. cirrhosis
14. macroprolactinemia: see text

[a] hyperprolactinemia from causes other than prolactinomas rarely exceeds 200 ng/ml
[b] always R/O pregnancy as a cause of amenorrhea & hyerprolactinemia in a female with reproductive potential

PRL being due to a prolactinoma is equal to one half the PRL. Also, a very large tumor with a modest elevation of PRL suggests stalk effect and not a prolactinoma since large prolactinomas usually have a very high PRL. Persistent post-op PRL elevation may occur even with total tumor removal as a result of stalk injury (usually ≤ 90 ng/ml; stalk effect is doubtful if PRL > 150). For stalk effect, follow these patients, do not use bromocriptine.

52.2.4 Specialized endocrinologic tests

Cushing's syndrome

Table 52.5 Basis for biochemical tests in Cushing's syndrome (CS)

- normally, low dose DMZ suppress ACTH release through negative feedback on hypothalamic-pituitary axis, reducing urine and serum corticosteroids
- in ≥ 98% of cases of Cushing's syndrome, suppression occurs, but at a much higher threshold
- adrenal tumors and most (85–90%) cases of ectopic ACTH production (especially bronchial Ca) will not suppress even with high dose DMZ
- ACTH response to CRH is exaggerated in CS
- DMZ does not interfere with measurement of urinary and plasma cortisol and 17-hydroxycorticosteroids

Tests for hypercortisolism

These tests are used to determine if *hypercortisolism* (Cushing's syndrome, CS) is present or not, regardless of etiology. Usually only needed if the screening 24-hr urine free cortisol (p. 876) is equivocal (the basis of these tests is shown in ▶ Table 52.5).

1. overnight *low-dose* dexamethasone (DMZ) suppression tests[22]:
    a) overnight low dose test: give DMZ 1 mg PO @ 11 P.M. and draw serum cortisol the next day at 8 A.M. Results:

    - cortisol < 1.8 mcg/dl (note: this is the currently accepted normal value; previously it was 5 mcg/dl): Cushing's syndrome is ruled out (except for a few patients with CS who suppress at low DMZ doses, possibly due to low DMZ clearance[23])
    - cortisol 1.8–10 mcg/dl: indeterminate, retesting is necessary
    - cortisol > 10 mcg/dl: CS is probably present. False positives can occur in the so-called pseudo-Cushing's state where ectopic CRH secretion produces hyperplasia of pituitary corticotrophs that is clinically indistinguishable from pituitary ACTH-producing tumors (requires further testing[23]). Seen in: 15% of obese patients, in 25% of hospitalized and chronically ill patients, in high estrogen states, in uremia, and in depression. The combined DMZ-CRH test can be used to identify this (see reference[23]). False positives also may occur in alcoholics or patients on phenobarbital or phenytoin due to increased metabolism of DMZ caused by induced hepatic microsomal degradation
  - b) 2 day low-dose test (used when overnight test is equivocal): give DMZ 0.5 mg PO q 6 hrs for 2 days starting at 6 A.M.; 24 hr urine collections are obtained prior to test and on the 2nd day of DMZ administration. Normal patients suppress urinary 17-hydroxycorticosteroids (OHCS) to less than 4 mg/24 hrs, whereas ≈ 95% of patients with CS have abnormal response (higher amounts in urine)[23]

2. 11 PM salivary cortisol: this is the time of the usual cortisol nadir. Test must be run at NIH-approved lab. Accuracy is as good as low-dose DMZ suppression test

Distinguishing Cushing's disease from ectopic ACTH secretion

These tests are used to distinguish primary Cushing's disease (CD) (pituitary ACTH hypersecretion) from ectopic ACTH production and adrenal tumors (may be required since 40% of CD patients have a normal MRI[1])

1. random serum ACTH: if < 5 ng/L indicates ACTH independent CS (e.g., adrenal tumor). Not sensitive or specific due to variability of ACTH levels
2. abdominal CT: usually shows unilateral adrenal mass with adrenal tumors, or normal or bilateral adrenal enlargement in ACTH-dependent cases
3. *high-dose* dexamethasone (DMZ) suppression test: (NB: up to 20% of patients with CD do not suppress with high-dose DMZ. Phenytoin may also interfere with high-dose DMZ suppression[24])
   - a) overnight high-dose test: obtain a baseline 8 A.M. plasma cortisol level
   - b) then give DMZ 8 mg PO @ 11 P.M. and measure plasma cortisol level the next morning at 8 A.M.
   - c) in 95% of CD cases plasma cortisol levels are reduced to < 50% of baseline, whereas in ectopic ACTH or adrenal tumors it will usually be unchanged
4. **metyrapone** (Metopirone®) test: performed on an inpatient basis. Give 750 mg metyrapone (suppresses cortisol synthesis) PO q 4 hrs for 6 doses. Most patients with CD will have a rise in 17-OHCS in urine of 70% above baseline, or an increase in serum 11-deoxycortisol 400-fold above baseline
5. corticotropin-releasing hormone (CRH) stimulation test: CD responds to exogenous CRH 0.1 mcg/kg IV bolus with even further increased plasma ACTH and cortisol levels; ectopic ACTH and adrenal tumors do not[25]
6. inferior petrosal sinus (IPS) sampling (or cavernous sinus sampling is preferred by some): done by interventional neuroradiologist. Uses a microcatheter to measure ACTH levels on each side at baseline, and then at 2, 5, and 10 minutes after stimulation with IV CRH (with simultaneous peripheral ACTH levels at each interval). General information:
   - a) IPS sampling is not needed when the following criteria of CD are met[26]:
     - ACTH-dependent Cushing's disease
     - suppression with high-dose dexamethasone test (see above)
     - visible PitNET/adenoma on MRI
   - b) may also determine likely side of a microadenoma within the pituitary (thus may be able to avoid bilateral adrenalectomy, which requires lifelong gluco- and mineralo-corticoid replacement and risks Nelson's syndrome (p. 869) in 10–30%). 15–30%[1] of the time this test falsely lateralizes the tumor due to the communication through the circular sinus
   - c) a baseline IPS ACTH to peripheral ACTH ratio > 1.4:1 is consistent with primary Cushing's disease
   - d) a post CRH ratio > 3 is also consistent with primary Cushing's disease
   - e) complication rate: 1–2%, includes puncture of the sinus wall

Assessing cortisol reserve

1. cosyntropin stimulation test[27]:

   - a) draw a baseline cortisol level (fasting is not required; test can be performed at any time of day)
   - b) give cosyntropin (Cortrosyn®) (a potent ACTH analogue) 1 ampoule (250 mcg) IM or IV
   - c) then check cortisol levels at 30 mins (optional) and at 60 mins
   - d) normal response: peak cortisol level > 18 mcg/dl AND an increment > 7 mcg/dl, or a peak > 20 mcg/dl regardless of the increment
   - e) subnormal response: indicates adrenal insufficiency. In primary adrenal insufficiency, pituitary ACTH secretion will be elevated. In secondary adrenal insufficiency, chronically reduced ACTH causes adrenal atrophy and unresponsiveness to acute stimulation with this exogenous ACTH analogue
   - f) normal response: rules out primary and overt secondary adrenal insufficiency, but may be normal in *mild* cases of reduced pituitary ACTH or *early* after pituitary surgery where adrenal atrophy has not occurred. In these cases further testing may be positive: see metyrapone test (p. 902) or ITT (see below)
2. insulin tolerance test (ITT): "gold standard" for assessing integrity of the hypothalamic-pituitary-adrenal axis. Cumbersome to do. Abnormal in 80% of CS. Assesses ACTH, cortisol & GH reserve
   - a) rationale: an appropriate cortisol increment in response to insulin-induced hypoglycemia suggests patient will also be able to respond to other stresses (acute illness, surgery…)
   - b) contraindications: seizure disorder, ischemic cardiac disease, untreated hypothyroidism
   - c) pre-test preparation: D/C estrogen replacement for 6 weeks prior to test. Have 50 ml of D50 and 100 mg IV hydrocortisone available during test
   - d) protocol: give regular insulin 0.1 U/kg IV push, and draw blood for glucose, cortisol and GH at 0, 10, 20, 30, 45, 60, 90 and 120 mins (monitor blood sugar by fingerstick during test, and give IV glucose if patient becomes symptomatic). If fingerstick blood sugar is not < 50 mg/dl by 30 minutes and patient is asymptomatic, give additional regular insulin 5 U IVP. There must be 2 specimens after adequate hypoglycemia
   - e) results:
     - if adequate hypoglycemia (< 40 mg/dl) was not accomplished: cortisol or GH deficiency cannot be diagnosed
     - normal: cortisol increment > 6 mcg/dl to a peak > 20
     - peak cortisol = 16–20: steroids needed only for stress
     - peak cortisol < 16: glucocorticoid replacement needed
     - Cushing syndrome: increment < 6

Acromegaly

For suspected acromegaly, the most useful test is an IGF-1 level.

1. insulin-like growth factor-1 (IGF-1) (formerly somatomedin-C) level: an excellent integrative marker of average GH secretion. Normal levels depend on age (peaking during puberty), gender, pubertal stage and lab. Typical fasting levels by age are shown in ▶ Table 52.6. Estrogen may suppress IGF-1 levels

Table 52.6 Normal IGF-1 by age

Age (yrs)	Level (ng/ml)
1–5	49–327
6–8	52–345
9–11	74–551
12–15	143–996
16–20	141–903
21–39	109–358
40–54	87–267
> 54	55–225

2. growth hormone (GH): normal basal fasting level is < 5 ng/ml. In patients with acromegaly, GH is usually > 10 ng/ml but can be normal. Normal basal levels do not reliably distinguish normal patient from GH deficiency.[28] Furthermore, due to pulsatile secretion of GH, normal patients may have sporadic peaks up to 50 ng/ml.[29] Occasionally acromegaly may be present even with GH

levels as low as 37 pg/ml.[30] ∴ random GH levels are not generally useful for diagnosing acromegaly (see above for IGF-1)

3. other tests used uncommonly
   a) oral glucose suppression test (OGST): less precise and more expensive than measuring IGF-1; however, may be more useful than IGF-1 for monitoring initial response to therapy. GH levels are measured at 0, 30, 60, 90, and 120 minutes after a 75 gm oral glucose load. If the GH nadir is not < 1 ng/ml, the patient is acromegalic.[31,32] GH suppression may also be absent with liver disease, uncontrolled DM & renal failure. ✖ Relatively contraindicated in patients with DM and high glucose levels
   b) growth-hormone releasing hormone (GHRH) levels: may help diagnose ectopic GH secretion in a patient with proven acromegaly with no evidence of pituitary tumor on imaging. If an extrapituitary source is suspected, chest and abdominal CT and/or MRI should also be obtained[33]
   c) GHRH stimulation test: results may be discordant in up to 50% of patients with acromegaly[31] and is thus rarely used (as of this writing, pharmaceutical production of GHRF has been discontinued)
4. octreotide scan: SPECT imaging 4 and 24 hours after injection with 6.5 mCi of indium-111 OctreoScan, a somatostatin receptor imaging agent

52.2.5 Radiographic evaluation

General information

Practice guideline: Imaging of PitNET/adenomas*

- Level II[34]:
  - MRI without and with contrast with dedicated images through the pituitary spaced 1–2 mm apart is the imaging modality of choice
  - thin-cut CT through the sella/sphenoid region and/or CTA may be used to augment the MRI (or may be used in cases where MRI is contraindicated)
- Level III[34]: 3 T MRI scanners may provide finer anatomic resolution relative to 1.5 T scanners

* these guidelines were developed for suspected *nonfunctioning* PitNET/adenomas, principles may not be generalizable

52

≈ 50% of pituitary tumors causing Cushing's syndrome are too small to be imaged on CT or MRI at the time of initial presentation (therefore endocrinologic testing is required to prove the pituitary origin). See differential diagnosis of intrasellar lesions (p. 1653); some are indistinguishable radiographically.

Normal AP diameter of pituitary gland: female of childbearing age (≈ 13–35 yrs): ≤ 11 mm, for all others normal is ≤ 9 mm. (Note: pituitary glands in adolescent girls may be physiologically enlarged (mean height: 8.2 ± 1.4 mm) as a result of hormonal stimulation of puberty.[35]

MRI

MRI is the maging test of choice for pituitary tumors.

Ordering the MRI:

1. a pituitary protocol (p. 241) is especially helpful when searching for a microadenoma
2. for follow-up of macroadenomas: routine coronal and sagittal pituitary MRI without and with contrast with detailed coronal cuts through the pituitary often suffices (i.e., dynamic images are not required unless there is a specific need to visualize the pituitary gland as distinct from the tumor)

Findings: MRI provides information about invasion of cavernous sinus, and about location and/or involvement of parasellar carotids (▶ Fig. 52.1). MRI may fail to demonstrate microadnomas in 25–45% of cases of Cushing's disease.[36] 3 T vs. 1.5 T MRI: based on 5 cases of Cushing's disease, a 3 T MRI showed the adenoma more clearly in 2 cases, in 1 case it showed the tumor on the correct side opposite to where the 1.5 T MRI showed it, and in 2 cases neither 1.5 T nor 3 T MRI could show the microadenoma.[37]

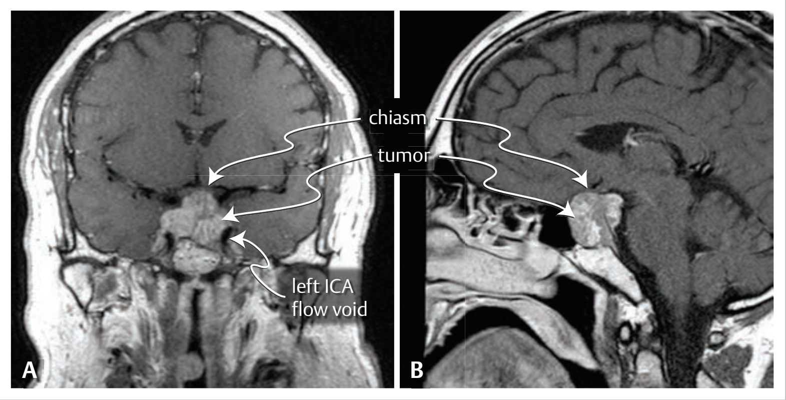

Fig. 52.1 Pituitary macroadenoma.
This 3 cm diameter tumor has grown superiorly through the diaphragma sella and is minimally elevating the optic chiasm. The tumor has invaded both cavernous sinuses, and flow voids within the cavernous segment of the internal carotid arteries (ICAs) are shown.
Image: T1 MRI with contrast. A: Coronal, B: Sagittal.

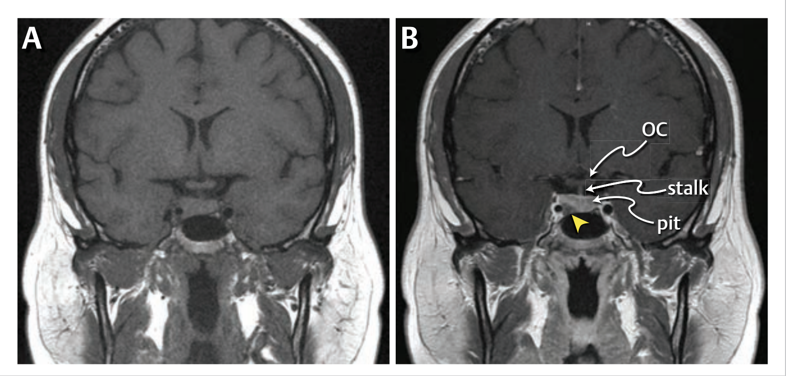

Fig. 52.2 Pituitary microadenoma in a 27-year-old woman with Cushing's disease.
Coronal MRI. A: T1WI noncontrast, B: T1WI with contrast.
The tumor is not visible on the noncontrast image (A), but shows up on the contrast image (B) as a hypointense area (*yellow arrowhead*) when scanned shortly after the administration of contrast.
Abbreviations: OC = optic chiasm, stalk = pituitary stalk, pit = pituitary gland.

Microadenoma: 75% are low signal on T1WI, and high signal on T2WI (but 25% can behave in any way, including completely opposite to above). Enhancement is very time-dependent. Imaging must be done with 5 minutes of contrast administration to see a discrete microadenoma. Initially, gadolinium enhances the normal pituitary (no blood-brain barrier) but *not* the pituitary tumor (▶ Fig. 52.2). After ≈ 30 minutes, the tumor enhances about the same. Dynamic MRI scans have been used to increase the sensitivity (contrast is injected while the MRI scanner is running).

Neurohypophysis: normally is high signal on T1WI[38] (possibly due to phospholipids). Absence of this "bright spot" often correlates with diabetes insipidus as may occur with autoimmune hypophysitis (p. 1656); however, failure to image the bright spot is not uniformly abnormal.

Deviation of the pituitary stalk may also indicate the presence of a microadenoma. Normal thickness of the pituitary stalk is approximately equal to basilar artery diameter. Thickening of stalk is usually NOT adenoma; differential diagnosis for a thickened stalk: lymphoma, autoimmune hypophysitis (p. 1656), granulomatous disease, hypothalamic glioma.

Cavernous sinus invasion: numerous criteria have been proposed to determine the degree of cavernous sinus invasion which correlates with degree of resectability. Knosp et al.[39] utilized 3 lines (MLL, MNL, and LL) as shown in ▶ Fig. 2.11, and the tumor invasion is graded as shown in ▶ Table 52.7.

Table 52.7 Knosp et al.[39] grading of cavernous sinus invasion as modified by Micko et al.[40] in 137 tumors grade ≥ 1

Grade	Feature	Percent invasive[a]	GTR	ER
0	tumor does not cross lateral to the MLL	0%		
1	tumor crosses the MLL but not the MNL (intercarotid line)	1.5%	83%	88%
2	tumor crosses MNL but not LL	10%	71%	60%
3A[b]	tumor extends lateral to LL superiorly (above ICA)	26%	85%	67%
3B[b]	tumor extends lateral to LL inferiorly (below ICA)	71%	64%	0%
4	tumor wraps completely around the intracavernous ICA	100%	0%	0%

[a] percentage of tumors in the grade that were invasive

[b] the original grade 3 was subdivided into 3A and 3B by Micko et al.[40]

Abbreviations: GTR = gross total resection, ER = endocrinologic remission in functioning tumors, MLL = medial line, MNL = median line (intercarotid line), LL lateral line (see ▶ Fig. 2.11 for illustration of the lines used)

CT

Generally superseded by MRI. May be appropriate when MRI is contraindicated (e.g., pacemaker). May also be considered as pre-op assessment in cases for transsphenoidal surgery (demonstrates shenoid septal anatomy with more detail[34]). If MRI cannot be done, consider also CTA to demonstrate parasellar carotid arteries and in questionable cases to R/O giant aneurysm which may mimic an adenoma (p. 1655).

Calcium in a pituitary tumor usually signifies previous hemorrhage or infarction within the tumor.

Angiography

Sometimes used pre-op for transsphenoidal surgery to localize the parasellar carotids (note: generally supplanted by CTA). NB: MRI also provides this information, and evaluates invasion of cavernous sinuses, usually obviating the need for angiography.

Skull X-ray

A lateral skull X-ray may help define the bony anatomy of the sphenoid sinus in cases where transsphenoidal surgery is contemplated (currently, CT scan is usually preferred).

53 PitNET/Adenomas – General Management

53.1 Management/treatment recommendations

53.1.1 General information

For pituitary apoplexy (p. 865). For large invasive adenomas (p. 886).

Note: Prolactinoma is the only pituitary tumor for which medical therapy (dopamine agonist) is the primary treatment modality (in certain cases).

Hormone replacement therapy (HRT)

HRT may be required for patients with documented endocrine deficits pre-op or post-op in cases where pituitary function is not normal. Critical issues:

1. corticosteroids
   a) indications: inadequate cortisol reserve as demonstrated by failing a cosyntropin stimulation test (viz. failure to achieve a peak cortisol level > 18 mcg/dl in response to cosyntropin) (p. 880)
   b) may start cortisol immediately after bloodwork for cosyntropin test is drawn (do not need to wait for test results)—then, when test results are available, continue or stop therapy based on test results
   c) ℞ physiologic replacement dose: cortisol 20 mg PO q AM and 10 mg PO q 4 PM. Stress doses may be needed (p. 155) in some situations
2. thyroid hormone replacement
   a) ✖ thyroid replacement can precipitate adrenal crisis if started before cortisol in a patient with adrenal insufficiency (as may occur in panhypopituitarism)
      - ∴ do a cosyntropin stimulation test (p. 880) and start cortisol
      - thyroid replacement may be initiated after 1 full day of cortisol. ℞: start with synthroid 125 mcg/d
   b) although there are warnings not to do surgery on a hypothyroid patient, the reality is that it takes 3–4 weeks for adequate replacement, and hypothyroid patients frequently undergo surgery before then with no untoward effect
3. testosterone replacement: may increase intratumoral levels of estradiol, which may promote tumor growth. ∴ wait for stabilization of tumor before starting

53.1.2 Management of large, invasive adenomas

See reference.[1]

1. prolactinomas
   a) dopamine agonists (DA) (p. 888) unless there is unstable deficit
   b) for unstable deficit, or if the tumor does not respond to DAs: debulk the tumor transsphenoidally and then rechallenge with DA therapy
2. tumors secreting growth hormone or ACTH: an aggressive surgical approach is indicated with these tumors since the secretion product is harmful and effective medical adjuvants are lacking
   a) pre-treat invasive GH-secreting tumors with somatostatin analogue therapy before surgery to reduce surgical risks (general and cardiac)
   b) elderly patients or tumors > 4 cm diameter: debulk tumor transsphenoidally and/or adjuvant therapy (XRT and/or medications)
   c) young age and size < 4 cm: radical surgery (may utilize a cranio-orbito-zygomatic skull base approach; may be curative)
3. nonfunctional adenomas
   a) elderly patient: expectant management is an option, with intervention for signs of progression (radiographic or neurologic)
   b) central tumor or elderly patient with progression: transsphenoidal tumor debulking and/or XRT (residual tumor in the region of the cavernous sinus may show little or no change over several years, and with these nonfunctional tumors, there is less risk in following them than if there is a harmful secretion product)
   c) parasellar tumor and/or young age: radical surgery (often not curative)

53.1.3 Nonfunctioning PitNET/adenomas—management

Surgical indications

Practice guideline: Management of nonfunctioning PitNET/adenomas (NFPAs)

Level III[2]: surgical resection is recommended as the primary treatment modality for *symptomatic** NFPAs

* there was insufficient evidence to make recommendations for asymptomatic NFPAs

Surgical resection is recommended for *symptomatic* NFPAs (based on a large amount of class III data), as opposed to limited class III evidence that showed inconsistent benefits for: observation alone (2 studies), primary XRT (3 studies) or primary medical treatment (8 studies) for improving vision, H/A, hypopituitarism or tumor volume.[2]

Literature on nonsurgical treatment modalities for NFPAs

- medical management: reported tumor response rates using dopamine agonists (e.g., bromocriptine) in 0–60% of cases, somatostatin analogs (e.g., Octreotide) in 12–40%, and combination therapy in 60%.[2] These agents are therefore not recommended as primary treatment due to lack of a significant and consistent response[2]
- XRT: studies have not shown equivalence or superiority of XRT as primary management compared to surgical management. XRT has been demonstrated to be an effective adjuncdtive tharapy for post-op residual tumor or recurrence (p. 893)
- natural history: NFPA *micro*adenomas have low growth propensity (estimated 3.2-12.5%), whereas ≈ 36% of NFPA *macro*adenomas enlarged (follow-up ranging 32-85 months).[3,4] Of the enlarging macroadenomas, 45% were asymptomatic. A minority of tumors actually shrink with time. Two studies showed tumor progression in 40–50%, and 21–28% required surgery.[5,6] Observation only is not recommended for *symptomatic* NFPAs[2]

Follow-up recommendations for NFPAs managed not meeting surgical criteria

Suggested management for incidental (asymptomatic) NFPAs that do not meet surgical criteria:

1. frequency of follow-up pituitary-MRI imaging[7]
   a) for microadenoma (≤ 1 cm maximal diameter): years 1, 2, 5 and ± 10 after the initial study, less frequently thereafter
   b) for macroadenoma (> 1 cm diameter): 6 months after initial study and then, if stable, annually for an additional 3 years, and then less frequently thereafter
2. duration of follow-up MRI: because growth may be very delayed, Dekkers recommended surveillance imaging for a total of 22 years[5]

Surgical indications for nonfunctioning pituitary macroadenomas

1. tumors causing symptoms by mass effect: visual field deficit (classically: bitemporal hemianopsia, panhypopituitarism)
2. some surgeons recommend surgery for macroadenomas that elevate the chiasm even in the absence of endocrine abnormalities or visual field deficit because of the possibility of injury to the optic apparatus
3. see invasive pituitary macroadenomas (p. 855)
4. acute and rapid visual or other neurologic deterioration. May represent ischemia of the chiasm, or tumor hemorrhage/infarction causing expansion (pituitary apoplexy (p. 865)). The immediate concern is irreversible blindness (hypopituitarism, while serious, can be treated with replacement therapy). Visual loss usually requires *emergent* decompression. Some surgeons feel that a transcranial approach is necessary, but transsphenoidal decompression is usually satisfactory[1,8]
5. to obtain tissue for pathological diagnosis in questionable cases

6. Nelson's syndrome (p. 869)
   a) surgery (transsphenoidal or transcranial): the primary treatment. The aggressiveness of the tumor sometimes requires total hypophysectomy
   b) XRT (possibly SRS) is used following subtotal excision
   c) medical therapy is usually ineffective. Agents that could be considered include[9]: dopamine agonists, valproic acid, somatostatin analogues, rosiglitazone, and serotonin agonists

53.1.4 Prolactinomas—management

Management guidelines

Prolactinomas are essentially the only PitNET/adenoma for which medical therapy is sometimes the primary treatment modality.

1. prolactin level (PRL) < 500 ng/ml in tumors that are not extensively invasive (see below for invasive tumors): PRL may be normalized with surgery
2. PRL > 500 ng/ml: the chances of normalizing PRL surgically are very low.[10] Algorithm:
   a) if no acute *progression* (worsening vision…), an initial attempt at purely medical control should be made as the chances of normalizing PRL surgically with pre-op levels > 500 ng/ml are very low[10] (these tumors may shrink dramatically with bromocriptine)
   b) response should be evident by 4–6 weeks (significant decrease in PRL, improvement of visual deficits, or shrinkage on MRI)
   c) if tumor *not* controlled medically (≈ 18% will not respond to bromocriptine, an attempt with cabergoline may also be considered): surgery followed by reinstitution of medical therapy may normalize PRL

Medical management with dopamine agonists

Dopamine agonists

Side effects[11]: (may vary with different preparations) nausea, H/A, fatigue, orthostatic hypotension with dizziness, cold induced peripheral vasodilatation, depression, nightmares and nasal congestion. Side effects are more troublesome during the first few weeks of treatment. Tolerance may be improved by bedtime dosing with food, slow dose escalation, sympathomimetics for nasal congestion, and acetaminophen 1–2 hrs before dosing to reduce H/A. Psychosis and vasospasm are rare side effects that usually necessitate discontinuation of the drug.

Drug info: Bromocriptine (Parlodel®)

A semi-synthetic ergot alkaloid that binds to dopamine receptors (dopamine agonist) on normal and tumor lactotrophs, inhibiting synthesis and secretion of PRL and other cell processes resulting in decreased cell division and growth. Bromocriptine lowers prolactin level, regardless of whether the source is an adenoma or normal pituitary (e.g., as a result of stalk effect), to < 10% of pretreatment values in most patients. It also frequently reduces the tumor size in 6–8 weeks in 75% of patients with macroadenomas, but only as long as therapy is maintained and only for tumors that actually produce prolactin. Only ≈ 1% of prolactinomas continue to grow while the patient is on bromocriptine. Prolactinomas may enlarge rapidly upon discontinuation of the drug. However, permanent normoprolactinemia can occur (see below).

Pregnancy issues: bromocriptine can restore fertility. Continued therapy during pregnancy is associated with a 3.3% incidence of congenital anomalies and 11% spontaneous abortion rate which is the same as for the general population. Estrogen elevation during pregnancy stimulates hyperplasia of lactotrophs and some prolactinomas, but the risk of symptomatic enlargement of microadenomas and totally intrasellar macroadenomas is < 3%, vs. 30% risk for macroadenomas.[12]

Prolonged treatment with bromocriptine may reduce the chances of surgical cure if this should be chosen at a later date. With a microadenoma, one year of bromocriptine may reduce the surgical cure rate by as much as 50%, possibly due to induced fibrosis.[13] Thus, it is suggested that if surgery is to be done that it be done in the first 6 months of bromocriptine therapy. Shrinkage of large tumors due to bromocriptine may cause CSF rhinorrhea.[14] **Side effects:** see above.

℞: start with 1.25 mg (half of a 2.5 mg tablet) PO q hs (nighttime dosing reduces some side effects) (vaginal administration is an alternative). Add additional 2.5 mg per day as necessary (based on prolactin levels (PRLs)), making a dosage change every 2–4 weeks for microadenomas, or every 3–4 days for macroadenomas causing mass effect. Initial recheck of prolactin level after about 4 weeks at a reasonable dose to verify response. ★ To shrink large tumors or for extremely high PRLs, higher doses are usually needed initially (e.g., 7.5 mg TID for ≈ 6 mos), and then lower doses may be able to maintain normal levels (typical maintenance dosage: 5–7.5 mg daily (range: 2.5–15 mg) which may be given as a single dose or divided TID). **Supplied:** 2.5 mg scored tabs; 5 mg capsules.

Drug info: Cabergoline (Dostinex®)

An ergot alkaline derivative that is a selective D2 dopamine agonist (bromocriptine (see above) affects both D2 and D1 receptors).[15] The elimination half-life is 60–100 hrs which usually permits dosing 1–2 times weekly. Control of PRL and resumption of ovulatory cycles may be better than with bromocriptine.[16] **Side effects:** (see above) H/A and GI symptoms are reportedly less problematic than with bromocriptine. ✖ Cardiac valve disease[17] (incidence-rate ratio, 4.9; 95% CI) affecting the mitral, aortic, and tricuspid valves, possibly leading to regurgitation (the drug activates 5-HT2B receptors which induces prolonged mitogenic effects in fibromyoblasts, which may lead to valvular fibroplasia) which has not been observed at doses used for prolactinomas (it is associated with doses used for Parkinson's disease which are > 10 × pituitary doses): recommendation: do not discontinue cabergoline for this reason if dose is < 2 mg/wk. ✖Contraindications: eclampsia or preeclampsia, uncontrolled HTN. Dosage should be reduced with severe hepatic dysfunction.

℞: Start with 0.25 mg PO twice weekly, and increase each dose by 0.25 mg every 4 weeks as needed to control PRL (up to a maximum of 3 mg per week). Typical dose is 0.5–1 mg twice weekly. Some combine the total dose and give it once weekly. Initial recheck of prolactin level after about 4 weeks to verify response. **Supplied:** 0.5 mg scored tablets.

Response to medical treatment

Treatment response to DA is assessed with serial prolactin levels as shown in ▶ Table 53.1. It is uncommon for a prolactinoma to enlarge without an increase in prolactin level.[18]

Discontinuation of dopamine agonists: Long-term therapy with DA agonists has some cytocidal effect on pituitary tissue. In an early report, discontinuation of treatment after 24 months was associated with > 95% recurrence rate.[19] There is a 20–30% chance of normoprolactinemia off medication in select patients.[20]

Recommendations[20]: if response to DA agonist is satisfactory, treat for 1–4 years (microadenomas: check prolactin yearly, macroadenomas are more likely to grow and should be checked more often). Microadenomas or macroadenomas that are no longer visible on MRI are candidates for DA agonist withdrawal. For microadenomas: discontinue the drug; for macroadenomas: slowly taper the drug then discontinue. Recurrence rate is highest during 1st year, ∴ check prolactin levels and clinical symptoms every 3 months during the 1st year. Long-term follow up is required, especially for macroadenomas.

Table 53.1 Prolactin level (PRL) with DA agonist treatment

PRL (ng/ml)	Recommendation
< 20	maintain
20–50	reassess dose
> 50	consider surgery

53.1.5 Acromegaly—management

See references.[21,22,23]

Surgery

Surgery is the primary treatment modality for acromegaly when treatment is indicated.

1. asymptomatic elderly patients do not require treatment since there is little evidence that intervention alters life expectancy in this group
2. if no contraindications, *surgery* (usually transsphenoidal) is currently the best initial therapy (worse prognosis with macroadenomas), providing more rapid reduction in GH levels and

decompression of neural structures (e.g., optic chiasm) and improving the efficacy of subsequent somatostatin analogues.[23] Surgery is not recommended for elderly patients

3. medical therapy (p. 889); reserved for:
   a) patients not cured by surgery (reoperation doesn't work very often for acromegaly). Note: the definition of "biochemical cure" with acromegaly is not standardized (p. 903). Surgery is still helpful for those "not cured" and improves efficacy of other therapies; IGF-1 may take months to normalize after surgery
   b) or for those who cannot tolerate surgery (e.g., due to cardiomyopathy, severe hypertension, airway obstruction…; these contraindications may improve with medical therapy and then surgery can be reconsidered)
   c) or for recurrence after surgery or XRT
4. XRT (p. 893): for failure of medical therapy. Not recommended as initial treatment. NB: some practitioners use XRT for surgical failure, and employ medical therapy while waiting for XRT to have an effect. GH levels decline very slowly after XRT, see details and side effects (p. 888)

Medical therapy

Overview

1. dopamine agonists (DAs): although not mentioned in the AACE guidelines,[24] it may be worth trying a DA to see if the tumor responds (≈ 20% respond). If responsive, DAs are especially well suited for GH tumors that cosecrete PRL
   a) bromocriptine: (see below) although it benefits only a minority, a first line drug since it is cheaper than pegvisomant or octreotide and is given PO
   b) cabergoline (see above)
   c) others: lisuride, depo-bromocriptine (bromocriptine-LAR)
2. somatostatin analogues: indications: as initial medical therapy, or if no response to DAs, some also use this pre-op to improve surgical success rate
   a) octreotide and octreotide-LAR (see below)
   b) lanreotide, lanreotide SR and long-acting aqueous gel lanreotide (Autogel)
3. GH antagonists: pegvisomant (see below) considered for failures to above (not a primary therapy)
4. combination therapy: may be more effective than individual drugs. Pegvisomant or octreotide + dopamine agonist if no response to 1 drug alone

Specific agents

Drug info: Bromocriptine (Parlodel®)

Neoplastic somatotrophs may respond fortuitously to dopamine agonists and reduce growth hormone (GH) secretion. Bromocriptine lowers GH levels to < 10 ng/ml in 54% of cases, to < 5 ng/ml in only ≈ 12%. Tumor shrinkage occurs in only < 20%. Higher doses are usually required than for prolactinomas. If effective, the drug may be continued but should be periodically withdrawn to assess the GH level; see **Side effects** (p. 888). Estimated annual cost: $3,200 in the U.S.

℞ For growth hormone tumors that respond to bromocriptine, the usual dosage is 20–60 mg/d in divided doses (higher doses are unwarranted). The maximal daily dose is 100 mg.

Drug info: Octreotide (Sandostatin®)

A somatostatin analogue that is 45 times more potent than somatostatin in suppressing GH secretion but is only twice as potent in suppressing insulin secretion, has a longer half-life (≈ 2 hrs after SQ injection, compared to ≈ minutes for somatostatin), and does not result in rebound GH hypersecretion. GH levels are reduced in 71%, IGF-1 levels are reduced in 93%. 50–66% have normal GH levels, 66% achieve normal IGF-1 levels. Tumor volume reduces significantly in about 30% of patients. Many symptoms including H/A usually improve within the first few weeks of treatment. Annual cost to the patient: at least ≈ $7,800 in the U.S. Usually given in combination with bromocriptine.

After 50 mcg SQ injection, GH secretion is suppressed within 1 hr, nadirs at 3 hrs, and remains reduced for 6–8 hrs (occasionally up to 12 hrs). **Side effects:** reduced GI motility and secretion, diarrhea, steatorrhea, flatulence, nausea, abdominal discomfort (all of these usually remit in 10 days), clinically insignificant bradycardia in 15%, cholesterol *cholelithiasis* (in 10–25%) or bile sludge.

Asymptomatic stones require no treatment and routine ultrasonography is not required. Mild hypothyroidism or worsening of glucose intolerance may occur.

℞: Start with 50–100 mcg SQ q 8 hrs. Increase up to a maximum of 1500 mcg/d (doses > 750 mcg/d are rarely needed). Average dose required is 100–200 mcg SQ q 8 hrs.

Sandostatin LAR Depot: long acting release (LAR) form given by IM injection. ℞: give a test dose of *short acting* octreotide SQ in the office, and if no reaction (e.g., N/V...) begin LAR injections with 20 mg IM q 4 weeks, increase to 30 mg if GH > 5 mU/L just before 4th dose. Control can be achieved in some patients with dosing q 8–12 weeks.[25]

Drug info: Pegvisomant (Somavert®)

A genetically engineered competitive GH-receptor antagonist. Treatment for ≥ 12 mos results in normal IGF-1 levels in 97% of patients.[26] No change in pituitary tumor size has been observed.[27] Indications: failure of somatostatin in patient with GH secreting adenoma (patient is switched to pegvisomant, it is not added to regimen). **Side effects:** significant but reversible liver function abnormalities occur in < 1%. Serum GH typically increases for 5–6 months and then stabilizes, probably as a result of loss of negative feedback on IGF-1 production. Antibodies to GH occured in 17%, but tachyphylaxis was not observed

℞: 5–40 mg/d SQ (dose must be titrated to keep IGF-1 in the normal range, to avoid GH deficiency conditions).

53.1.6 Cushing's disease—management

Management algorithm

1. if pituitary MRI shows a mass: transsphenoidal surgery
2. if pituitary MR is negative (up to 40% of patients with Cushing's disease have negative MRI): perform inferior petrosal sinus (IPS) sampling (p. 880)
   a) if IPS sampling is positive: surgery
   b) if IPS sampling is negative: look for extra-pituitary source of ACTH (abdominal CT)
3. if pituitary surgery is performed but biochemical cure—see criteria (p. 903)—is not obtained with surgery:
   a) unlike acromegaly, a partial reduction is not helpful to the patient
   b) consider re-exploration if pituitary source is still suspected
   c) stereotactic radiosurgery or medical therapy (see below)
   d) adrenalectomy in appropriate patients (see below)

Transsphenoidal surgery

Transsphenoidal surgery is the treatment of choice for most (medical therapy is inadequate as initial therapy since there is no effective pituitary suppressive medication). Cure rates are ≈ 85% for microadenomas (i.e., tumors ≤ 1 cm dia), but are lower for larger tumors. Even with microadenomas, *hemihypophysectomy* on the side of the tumor is usually required for cure (the tumor is difficult to completely extirpate) with attendant increased risk of CSF leak. If this fails, consideration should then be for *total hypophysectomy*. Failure of total hypophysectomy prompts consideration for bilateral adrenalectomy (total hypophysectomy virtually eliminates risk of Nelson's syndrome following adrenalectomy—see below).

Stereotactic radiosurgery

Often normalizes serum cortisol levels. Useful for: recurrence after surgery, inaccessible tumors (e.g., cavernous sinus)[28]...

Adrenalectomy

Total bilateral adrenalectomy (TBA) corrects hypercortisolism in 96–100%[9] (unless there is an extra-adrenal remnant), but lifelong gluco- and mineralo-corticoid replacement are required and up to

30% develop Nelson's syndrome (p. 869) (incidence reduced by total hypophysectomy or possibly by pituitary XRT).

Indications: continued hypercortisolism with:

1. non-resectable PitNET/adenoma
2. failure of medical therapy to control symptoms after transsphenoidal surgery
3. life-threatening Cushing's disease (CD)
4. CD with no evidence of pituitary tumor; testing should include high-dose DMZ suppression test (p. 880) and/or inferior petrosal sinus sampling (p. 880)

Follow-up after TBA to rule out Nelson's syndrome: there is no standardized regimen. Suggestion: check serum ACTH levels q 3–6 months × 1 year, q 6 months × 2 years, q year thereafter. A pituitary MRI is done if an ACTH level is > 100 ng/L; otherwise, annual MRIs are sufficient[29] × 3 years and then if ACTH levels remain low, get an MRI every other year.

Medical therapy

For patients who fail surgical therapy or for whom surgery cannot be tolerated, medical therapy and/or radiation are utilized. Occasionally may be used for several weeks prior to planned surgery to control significant manifestations of hypercortisolism, e.g., diabetes, HTN, psychiatric disturbances… (p. 868).

Ketoconazole (Nizoral®)[11]: an antifungal agent that blocks adrenal steroid synthesis. The initial drug of choice. Over 75% of patients have normalization of urinary free cortisol and 17-hydroxycorticosteroid levels. **Side effects:** reversible elevations of serum hepatic transaminase (in 15%), GI discomfort, edema, skin rash. Significant hepatotoxicity occurs in 1 of 15,000 patients. See ▶ Table 8.2 for evidence of adrenal insufficiency.

℞ Start with 200 mg PO BID. Adjust dosage based on 24-hr urine free cortisol and 17-hydroxycorticosteroid levels. Usual maintenance doses 400–1200 mg daily in divided doses (maximum of 1600 mg daily).

Aminoglutethimide (Cytadren®)[11]: inhibits the initial enzyme in the synthesis of steroids from cholesterol. Normalizes urinary free cortisol in ≈ 50% of cases. **Side effects:** dose-dependent reversible effects include sedation, anorexia, nausea, rash and hypothyroidism (due to interference with thyroid hormone synthesis).

℞ Start with 125–250 mg PO BID. Effectiveness may diminish after several months and dose escalation may be needed. Generally do not exceed 1000 mg/d.

Metyrapone (Metopirone®): inhibits 11-β-hydroxylase (involved in one of the final steps of cortisol synthesis); may be used alone or in combination with other drugs. Normalizes mean daily plasma cortisol in ≈ 75%. **Side effects:** lethargy, dizziness, ataxia, N/V, primary adrenal insufficiency, hirsutism, and acne.

℞ Usual dose range is 750–6000 mg/d usually divided TID with meals. Initial effectiveness may diminish with time.

Mitotane (Lysodren®): related to the insecticide DDT. Inhibits several steps in glucocorticoid synthesis, and is cytotoxic to adrenocortical cells (adrenolytic agent). 75% of patients enter remission after 6–12 months of treatment, and the medication may sometimes be discontinued (however, hypercortisolism may recur). **Side effects:** may be limiting, and include anorexia, lethargy, dizziness, impaired cognition, GI distress, hypercholesterolemia, adrenal insufficiency (which may necessitate supernormal doses of glucocorticoids for replacement due to induced glucocorticoid degradation).

℞ Start with 250–500 mg PO q hs, and escalate dose slowly. Usual dose range is 4–12 g/d usually divided TID-QID. Initial effectiveness may diminish with time.

Cyproheptadine (Periactin®): a serotonin receptor antagonist that corrects the abnormalities of Cushing's disease in a small minority of patients, suggesting that some cases of "pituitary" Cushing's disease are really due to a hypothalamic disorder. Combined therapy with bromocriptine may be more effective in some patients. **Side effects:** sedation & hyperphagia with weight gain usually limit usefulness.

℞ Usual dosage range: 8–36 mg/d divided TID.

53.1.7 Thyrotropin (TSH)-secreting adenomas—management

General information

1. transsphenoidal surgery has been the traditional first-line treatment.[30] These tumors may be fibrous and difficult to remove[31]
2. for incomplete resection: post-op XRT is employed

3. if hyperthyroidism persists: medical therapy is added with agents including octreotide, bromocriptine (more effective for tumors that co-secrete PRL), and oral cholecystographic agents (which inhibit conversion of T4 to T3), e.g., iopanoic acid

Medical therapy

Normal and neoplastic anterior hypophyseal thyrotroph cells possess somatostatin receptors and most respond to octreotide (see below). Occasionally, beta-blockers or low-dose antithyroid drugs (e.g., Tapazole® (methimazole) ≈ 5 mg PO TID for adults) may additionally be required.

Octreotide (Sandostatin®)

Doses required are usually < than with acromegaly. TSH levels decline by > 50% in 88% of patients, and become normal in ≈ 75%. T4 and T3 levels decrease in almost all, with 75% becoming normal. Tumor shrinkage occurs in ≈ 33%.

℞ Start with 50–100 mcg SQ q 8 hrs. Titrate to TSH, T4 and T3 levels.

53.1.8 Gonadotropin secreting adenoma

This pertains to the rare patient who is symptomatic from gonadotropin hypersecretion.

Normal and neoplastic pituitary gonadotrophs have gonadotropin-releasing hormone (GnRH) receptors, and may respond to long-acting GnRH agonists (by down-regulating receptors) or GnRH antagonists, but significant reductions in tumor size does not occur.

53.2 Radiation therapy for PitNET/adenomas

53.2.1 General information

Conventional EBXRT usually consists of 40–50 Gy administered over 4–6 weeks.

Stereotactic radiosurgery (p. 1908) for PitNET/adenomas.

53.2.2 Side effects

Radiation injury to the remaining normal pituitary results in hypocortisolism, hypogonadism, or hypothyroidism in 40–50% of patients after 10 years. It may also injure the optic nerve and chiasm (possibly causing blindness), cause lethargy, memory disturbances, cranial nerve palsies, and tumor necrosis with hemorrhage and apoplexy. Cure rates but also complications are higher after proton beam therapy.

53.2.3 Recommendation

Radiation therapy should *not* be routinely used following surgical removal. Follow patient with yearly MRI. Treat recurrence with repeat operation. Consider radiation if recurrence cannot be removed and tumor continues to grow.

53.2.4 Sellar radiation therapy for specific PitNET/adenoma types

XRT for nonfunctioning pituitary tumors

In one series of 89 *nonfunctioning* pituitary tumors ranging 0.5–5 cm diameter (mean = 2 cm) not totally resected because of involvement of cavernous sinus (or other inaccessible sites), half were treated with radiation therapy (XRT). The recurrence rate was neither lower (and was actually higher) nor later in the XRT group.[32] However, another series of 108 pituitary macroadenomas found the recurrence rates shown in ▶ Table 53.2 which tend to favor radiation therapy.

When used, doses of 40 or 45 Gy in 20 or 25 fractions, respectively, is recommended.[34] The oncocytic variant of null cell pituitary tumors appears to be more radioresistant than the nononcocytic undifferentiated cell adenoma.[34]

Sellar radiation therapy for acromegaly

Not the preferred initial treatment. Works better with lower initial GH levels. In most patients, GH levels begin to fall during the first year after XRT, dropping by ≈ 50% after 2 years, and decrease gradually thereafter, reaching ≤ 10 ng/ml in 70% of patients after 10 years. It takes up to 20 years for 90%

Table 53.2 Recurrence rate of pituitary tumors removed transsphenoidally[a]

Extent of removal	Post-op XRT?	Recurrence rate
subtotal	no	50%
gross total		21%
subtotal	yes	10%
gross total		0

[a] 108 macroadenomas, 6 mos to 14 years follow-up[33]

of patients to achieve GH levels < 5 ng/ml. During this latency period, patients are exposed to unacceptably high levels of GH (octreotide may be used while waiting). Patients are also still at risk for radiation side effects mentioned above. Options include: EBRT, stereotactic radiosurgery (about equally effective). Estimated cost: $20,000.

Sellar radiation therapy for Cushing's disease

XRT corrects hypercortisolism in 20–40%, and produces some improvement in another 40%. Improvement may not be seen for 1–2 yrs post treatment.

54 PitNET/Adenomas – Surgical Management, Outcome, and Recurrence Management

54.1 Surgical treatment for PitNET/adenomas

54.1.1 Medical preparation for surgery

General principles

1. stress dose steroids: given to all patients during and immediately after surgery
2. hypothyroidism: ideally, hypothyroid patients should have > 4 weeks of replacement to reverse hypothyroidism; however:
   a) ✖ do not replace thyroid hormone until the adrenal axis is assessed; giving thyroid replacement to a patient with hypoadrenalism can precipitate adrenal crisis. If hypoadrenal, begin cortisol replacement first, may begin thyroid hormone replacement after 24 hours of cortisol
   b) surgery is done frequently on patients with hypothyroidism and appears to be tolerated well in the vast majority of cases

Pre-op orders

1. for transsphenoidal approach: Polysporin® ointment (PSO) applied in both nostrils the night before surgery
2. antibiotics: e.g., Unasyn® 1.5 gm (1 gm ampicillin + 0.5 gm sulbactam) IVPB at MN & 6 AM
3. steroids, either:
   a) hydrocortisone sodium succinate (Solu-Cortef®) 50 mg IM at 11 PM & 6 AM. On call to OR: hang 1 L D5LR + 20 mEq KCl/l + 50 mg Solu-Cortef at 75 ml/hr
   OR
   b) hydrocortisone 100 mg PO at MN & IV at 6 AM
4. intra-op: continue 100 mg hydrocortisone IV q 8 hrs

54.1.2 Surgical approaches—overview

54

Practice guideline: Surgical approaches and technology for nonfunctioning PitNET/adenomas (NFPAs)

Level III[1] recommendations include:
- transsphenoidal surgery (microscopic or endoscopic) is recommended for relief of symptoms
- if microsurgery is used initially, endoscopic visualization afterwards is recommended since it frequently reveals additional resectable tumor
- for invasive NFPAs with significant suprasellar, frontal or temporal involvement: combined transsphenoidal and transcranial surgery is recommended
- intraoperative MRI: may improve overall gross total resection; however, it is not recommended for estimating residual tumor volume because of a variable false-positive rate

✖ There was insufficient evidence to recommend[1]:
- neuronavigation
- introduction of intrathecal saline or air to augment delivery of suprasellar tumor during transsphenoidal approach
- to prevent postop CSF leak: perioperative CSF diversion, or a specific dural closure technique

1. transsphenoidal: requires no brain retraction, no external scar (aside from where a fat graft is procured, if used), and is normally an extra-arachnoid approach unless the diaphragma sella is broached. Usually the procedure of choice. Indicated for microadenomas, macroadenomas without significant extension laterally beyond the confines of the sella turcica, patients with CSF rhinorrhea, and tumors with extension into sphenoid air sinus
   a) sublabial

   b) trans-nares: for extremely small nares, an alotomy may be used to enlarge the exposure if necessary
2. transethmoidal approach[2 (p 343–50)]
3. transcranial approaches:
   a) indications: most pituitary tumors are operated by the transsphenoidal technique (see above), even if there is significant suprasellar extension. However, a craniotomy may be indicated for the following[3]:
      - minimal enlargement of the sella with a large suprasellar mass, especially if the diaphragma sellae is tightly constricting the tumor (producing a "cottage loaf" tumor) and the suprasellar component is causing chiasmal compression[4 (p 124)]
      - extrasellar extension into the middle fossa that is larger than the intrasellar component
      - unrelated pathology may complicate a transsphenoidal approach: rare, e.g., a parasellar aneurysm
      - unusually fibrous tumor that could not be completely removed on a previous transsphenoidal approach
      - recurrent tumor following a previous transsphenoidal resection
   b) choices of approach
      - subfrontal: provides access to both optic nerves. May be more difficult in patients with prefixed chiasm
      - frontotemporal (pterional): places optic nerve and sometimes carotid artery in line of vision of tumor. There is also incomplete access to intrasellar contents. Good access for tumors with significant unilateral extrasellar extension
      - ✖ subtemporal: usually not a viable choice. Poor visualization of optic nerve/chiasm and carotid. Does not allow total removal of intrasellar component

54.1.3 Transsphenoidal surgery

Booking the case: Transsphenoidal surgery

Also see defaults and disclaimers (p. 25) and pre-op orders (p. 896).

1. position: supine, horseshoe head rest or (especially if image-guided navigation is used) pin headholder
2. equipment:
   a) microscope
   b) C-arm (if used)
   c) image-guided navigation system (if used)
   d) endoscopy cart for cases performed endoscopically (surgeon preference)
3. instrumentation: transsphenoidal instrument set (usually includes speculum, curettes, long instruments including bipolars)
4. some surgeons use ENT to perform the approach and closure and for follow-up
5. post-op: ICU
6. consent (in lay terms for the patient—not all-inclusive):
   a) procedure: removal of pituitary tumor through the nose, possible placement of fat graft from abdomen
   b) alternatives: surgery through the skull (trans-cranial), radiation
   c) complications: CSF leak with possible meningitis, problems with pituitary hormones which may sometimes be permanent (which would require lifetime replacement therapy), injury to optic nerve with visual loss, injury to carotid artery with possible bleeding and/or stroke

Technique

General information

For pre- and post-op orders, see below.

Details of the surgery are beyond the scope of this text, see references.[4,5,6,7]

Intraoperative disasters

Usually related to loss of landmarks.[4] Can be minimized using intraoperative navigation or fluoroscopy to verify location.

- injury of carotid artery:
  - typically injured in lateral aspect of opening. Bone may be dehiscent over the ICA
  - signaled by profuse arterial bleeding
  - can usually be packed off, if fat/fascia graft from thigh or abdomen is available it may be used; otherwise use e.g., woven Surgicel®
  - the operation is halted, and a STAT post-op arteriogram must be done
  - if a pseudoaneurysm or site of injury is identified angiographically, it must be eliminated before a potentially lethal hemorrhage; accomplished either by endovascular techniques or by surgical trapping with clips above and below
- injury of basilar artery: with pulling on tissue adherent to the artery or reaching through sella and rongeuring
- opening through the clivus and erroneous biopsy of the pons
- opening through the floor of the frontal fossa with injury to the olfactory nerves and entry into inferior frontal lobes

Overview of the procedure

1. lumbar drain: may be used with some macroadenomas to inject fluid in order to help bring the tumor down (p. 896), also may be used for post-op CSF drainage (p. 899) following transsphenoidal repair of CSF fistula
2. medications (in addition to pre-op meds (p. 896)): intraoperatively 100 mg hydrocortisone IV bolus followed by 100 mg dripped in over 8 hrs
3. positioning
   a) elevate thorax 10–15°: reduces venous pressure
   b) head stabilization: if image-guided navigation is to be used, the head is placed in a Mayfield headholder, or a headband with registration array is attached and the head is placed on a horseshoe head rest. If no image guidance, a horseshoe headrest may be used
   c) position option 1: surgeon standing to right of patient
      - shoulder-roll
      - top of head canted slightly to left
      - neck position: For microscope: extend neck slightly with the head in either a Mayfield head-holder or on a horseshoe headrest. For endoscope: do not extend neck (more comfortable for holding instruments)
      - ET tube positioned down and to patient's *left* (to get it out of the way)
      - microscope: observer's eyepiece on the *left*
   d) position option 2: surgeon standing above patient's head: patient head pointing straight up towards ceiling, neck slightly extended
   e) abdomen or right thigh is prepped for possible fat graft if needed
4. C-arm fluoro: image-guided navigation can eliminate the need for fluoro. Orient the C-arm for a true lateral by aligning the mandibular rami and/or by superimposing the floor of the left and right frontal fossae. If this proves difficult, lay a Penfield 4 on the nasion oriented from lateral canthus to lateral canthus, then aim the fluoro to shoot "down the barrel" of the Penfield 4
5. after approach to floor of sella is complete (see below), outline the upper and lower boundaries of the sella using image navigation or fluoro using an instrument (e.g., suction tip)
6. opening the sellar floor:
   a) starting the opening: open *exactly* in the midline using the nasal septum as a landmark (NB: the septum of the sphenoid sinus is unreliable as a midline indicator, and often curves inferiorly towards one of the carotid arteries)
      - macroadenomas may have thinned the bone to the point that it just flakes off
      - otherwise, use a bayoneted chisel or high-speed diamond burr to start the opening
   b) use a Kerrison rongeur to expand the opening. ✖ CAUTION: stay away from the extreme lateral sella to avoid entering the cavernous sinus or injuring the carotid artery
7. coagulate the dura centrally in an "X" pattern (*NOT* " + " pattern) with bipolar cautery. Macroadenomas may cause yellowish discoloration of the dura directly over the tumor
8. consider aspirating through dura with a 20 gauge spinal needle to R/O large venous sinus (dura often has bluish discoloration), giant aneurysm (p. 1655), or empty sella
9. incise the dura in the "X" pattern in the midline with a #11 scalpel on a bayonetted handle
10. tumor removal for **macroadenoma**:
    a) gently bring tumor into the field with ring curettes, and remove with pituitary rongeurs or aspirate with suction. Some tumors are very fibrous and may be difficult to remove
    b) do not *pull* on the lateral component of the tumor with pituitary rongeur due to risk of injuring carotid artery

   c) if the suprasellar component will not come down, it may be brought down by having the anesthesiologist inject 5 ml aliquots of saline into a previously placed lumbar drain while monitoring blood pressure and pulse[4(p 135),8]
   d) once the tumor is debulked internally, try to develop a plane between the tumor capsule and the pituitary. A good place to start looking is inferiorly where the dura can be separated from the tumor capsule and then followed on the surface. Sometimes the tumor capsule cannot be removed due to severe bleeding
   e) complete tumor removal is often not possible, and the goal of the surgery then is "containment," with intractable post op re-growth treated with XRT
   f) endoscopic techniques and image-guided navigation may be employed to assist in removal of macroadenomas
11. tumor removal for microadenoma
   a) if the side of the tumor is known, begin exploration of the gland on that side by making incision with #11 blade and using a dissector to try and locate the tumor (like a "grain of rice in a blueberry")
   b) for Cushing's disease, if no tumor is identified on pre-op MRI[9]:
      - intraoperative ultrasound may help localize tumor in ≈ 70% of cases[10] (a specialized U/S probe is required)
      - if IPS sampling showed a lateralizing ACTH gradient: start with a paramedian incision on the side of the higher ACTH gradient; if no adenoma is encountered, the contralateral paramedian and then midline incisions are used to explore the gland
      - if IPS sampling and MRI do not suggest tumor location: the gland is explored sequentially with 2 paramedian incisions and then a midline incision
      - if the adenoma cannot be found, a hemihypophysectomy is performed on the side of higher ACTH levels if IPS sampling shows a lateralizing gradient, or on the side with more suspicious tissue on frozen section. Total hypophysectomy is not routinely performed[9]
   c) most adenomas are purplish-gray and easily aspirated; however, some may be more fibrous. The normal pituitary gland is firm and rubbery (the adenohypophysis is orange-pink, the neurohypophysis is a whitish-gray), and normally does not curette very easily
   d) use image guidance or fluoro to determine approximate location of diaphragma sellae. Do not go cephalad to this to avoid a CSF leak, to avoid entering the circular venous sinus in the dura here, and to avoid trauma to the optic chiasm
12. after removal of macroadenoma, check depth of tumor bed on fluoro or image guidance, and make sure it correlates with approximate tumor volume on pre-op MRI
13. the sella may be packed in a number of ways,[7] one method:
   a) if CSF leak occurs: place muscle or fat in defect within sella. Some recommend against the use of muscle because it always putrefies.[4(p 129)] Do not overpack to avoid recreating mass effect with the graft
   b) recreate the floor of the sella using nasal cartilage placed within the sella. Alternatively, a nonporous Medpor® polyethylene transsphenoidal sellar implant (Porex Surgical Products http://www.porexsurgical.com) may be used
   c) if CSF leak occurs pack sphenoid sinus with fat from abdomen (option: fat with fascia on surface)
   d) fibrin glue may optionally be used to help hold any of these components in place
   e) elaborate packing for closure is not mandatory if no CSF leak occurs during surgery

Approach to sphenoid sinus for microscopic removal

Often done by ENT co-surgeon. One method:

1. insert temporary speculum into nose. For this discussion, the right nares will be described
2. use endoscope to locate middle concha. Follow this posteriorly to identify os into sphenoid sinus, which is usually located posterior to and slightly above the posterior extent of the middle concha
3. inject local anesthetic with epinephrine to blanch mucosa
4. insert sickle knife into os with sharp side facing the septum (medially) and incise the mucosa as the knife is drawn outward
5. use a Freer to dissect the thusly created mucosal flaps off the medial septum (pull one up, the other down)
6. break through the posterior part of the septum so that both sides of the floor of the sphenoid sinus are exposed. Cartilage or bone from this step is saved to use later in reconstructing the floor of the sella if desired
7. open the floor of the sphenoid and take it all the way to the right os (you will probably not see the left os)

8. place the Hardy speculum or equivalent
9. strip mucosa off the walls of the sphenoid sinus using a Blakely and *slow* pulling motion

Endoscopic tumor removal

Advantages over microscopic removal: visualization is better, especially within tumor bed.

Disadvantages: most neurosurgeons have less facility with endoscopes compared to ENT surgeons. Lack of 3D visualization (may be overcome using 3D endoscopes). Need for single-handed technique (may be overcome by having assistant hold endoscope, or using an endoscope holder, e.g., Mitaka), need for a binasal approach if it is desired to use two hands for the actual surgery.

Recommendations (p. 896): Either endoscopic or microscopic approach is acceptable; however, after microscopic approach it is recommended that an endoscope be used at the time of the same surgery to visualize additional resectable tumor.[1]

54.1.4 Perioperative complications

1. hormonal imbalance:
   a) acute post-op concerns:
      - alterations in ADH: transient abnormalities are common—see typical post-op patterns (p. 902) – including DI. DI lasting > 3 mos is uncommon
      - cortisol deficiency → hypocortisolism → Addisonian crisis if severe
   b) long-term: hypopituitarism in ≈ 5% (retrospective series[11])
      - TSH deficiency → hypothyroidism → (rarely) myxedema coma if severe
      - adrenal insufficiency
      - deficiency of sex hormones → hypogonadotrophic hypogonadism
2. secondary empty sella syndrome (chiasm retracts into evacuated sella → visual impairment). Reoperation with gentle packing of fat into the sella may support the chiasm
3. hydrocephalus with coma[12]: may follow removal of tumors with suprasellar extension (transsphenoidally or transcranially). Consider ventriculostomy placement if hydrocephalus is present (even if not symptomatic). Possible etiologies:
   a) traction on the attached 3rd ventricle
   b) cerebral edema due to vasopressin release from manipulation of the pituitary and/or stalk
   c) tumor edema following resection
4. infection
   a) pituitary abscess[13,14]
   b) meningitis
5. CSF rhinorrhea (fistula): 3.5% incidence[15]
6. carotid artery rupture: rare. May occur intraoperatively (see above) or in delayed fashion after surgery, often ≈ day 10 post-op (due to breakdown of fibrin around carotid, or possibly due to rupture of a pseudoaneurysm created at surgery)
7. entry into cavernous sinus with possible injury of any structure within
8. nasal septal perforation

54.1.5 Frontotemporal (pterional) approach

A right-sided approach is usually employed (less risk to dominant hemisphere). Exceptions: when the left eye is the side of worse vision; if there is predominant left-sided tumor extension; if there is other pathology on the left (e.g., aneurysm).

Positioning is the same as for an ACoA aneurysm, as seen in ▶ Fig. 106.1, with the head turned 60° to the side. The frontal lobe is elevated, and the temporal tip is gently retracted posteriorly. Bridging veins to the temporal tip must be coagulated to avoid rupture, as for any pterional approach. The approach is similar to that for an ACoA aneurysm (i.e., more emphasis is placed on frontal lobe elevation than on temporal tip retraction), except that unlike ACoA aneurysm, exposure of the ICA is not needed because proximal control is not necessary.

The tumor capsule can usually be seen between the two optic nerves. The capsule is coagulated with bipolar cautery and is incised. The tumor is then debulked from within. By staying within the capsule, risk of injury to the pituitary stalk and optic chiasm is minimized. Significant amounts of tumor can be removed by aspiration if it is soft and suckable.

✖ Caution: the blood supply to the optic chiasm is from the inferior aspect. Skeletonizing the chiasm or attempting to tease away tumor adherent to it may worsen vision.

54.1.6 Postoperative management

"DI watch" (diabetes insipidus watch)

Following any surgery involving the pituitary gland, patients are at risk of developing DI (inadequate secretion of ADH) which can produce dangerous dehydration and hypernatremia (elevation of serum sodium $[Na^+]$). Therefore, these patients place on so-called "DI watch." One needs to be familiar with the 3 possible post-op patterns of ADH abnormalities (see typical patterns (p. 902)). DI watch consists of:

1. strict intake & output (I's & O's) q 1 hr
2. urine specific gravity (USG) q 4° and any time urine output (UO) > 250 ml/hr
3. serum electrolytes q 6 hours: watching primarily $[Na^+]$

Diagnostic criteria for DI: UO > 250 ml/hr × 2 hrs, *and* SG < 1.005.
DI is not present if USG > 1.005. In DI, USG is usually < 1.003.

Post-op orders

1. strict intake & output (I's & O's) q 1 hr
2. urine specific gravity (USG) q 4° and any time urine output (UO) > 250 ml/hr X 2 hours
3. activity: BR with HOB @ 30°
4. diet: ice chips PRN, advance to clear liquids as tolerated. For transspheonidal approach: patient is not to drink through a straw (to avoid negative pressure on sphenoid sinus with risk of promoting CSF fistula)
5. for transspheonidal approach: no incentive spirometry (for same reason as no straw)
6. IVF
   a) basal IVF: IV D5 1/2 NS + 20 mEq KCl/L at appropriate rate (75–100 ml/hr)
   b) NB: patients normally receive IV fluids at the beginning of an operation to "fill the tank" to avoid hypotension as a result of muscle relaxation. It is normal for patients to have a post-op diuresis as they eliminate excess fluids. As long as the urine SG is > 1.003 and urine output (UO) is < 250 ml/hr, aggressive fluid administration is usually not warranted
   c) if UO > 250 ml/hr X 2 hrs and USG < 1.005, the patient probably has diabetes insipidus (DI). If this occurs, in addition to the basal IVF, replace UO that is over the IV basal rate ml for ml with ½ NS and consider starting medication (see "meds" below)
   d) if UO is high and patient is not clearly in DI, an option is to replace only ≈ 2/3 of UO > basal IV rate with ½ NS
7. meds
   a) antibiotics: continue antibiotics until nasal packing is removed
   b) steroids (some surgeons routinely use post-op steroids until the adequacy of endogenous steroids is established, especially with Cushing's disease, see below). If this is EITHER:
      - hydrocortisone 50 mg IM/IV q 6 hrs, on POD #2 change to prednisone 5 mg PO q 6 hrs × 1 day, then 5 mg PO BID, D/C on POD #6
        OR
      - hydrocortisone 50 mg IM/IV/PO BID, taper 10 mg/dose/day to physiologic dose of 20 mg q AM and 10 mg q PM until adrenal axis assessed
   c) if DI develops, attempt to keep up with fluid loss with oral and/or IV fluids (see above). If rate is too high to continue IV or PO replacement (> 300 cc/hr × 4 hrs or > 500 cc/hr × 2 hrs), check urine SG and if < 1.005 then give a vasopressin preparation (see below, or see ▶ Table 5.7). ✖ Caution: danger of overtreating in case of triphasic response (p. 125). Use EITHER:
      - 5 U aqueous vasopressin (Pitressin®) IVP/IM/SQ q 6 hrs PRN
        OR
      - desmopressin (DDAVP®) injection SQ/IV titrated to UO. Usual adult dose: 0.5–1 ml (2–4 mcg) daily in 2 divided doses

      - ✖ AVOID tannate oil suspension (withdrawn from U.S. market in 1993), because it is a long acting preparation (and may overtreat) and has erratic absorption

      - THEN: (for transspheonidal approach or when patient is taking po for transcranial approach) when nasal packs out, EITHER

intranasal DDAVP (100 mcg/ml): range 0.1–0.4 ml (10–40 mcg) intranasally BID (typically 0.2 ml BID) PRN
OR
- clofibrate (Atromid S®) 500 mg PO QID (does not always work)

8. labs: electrolytes with osmolarity q 6 hrs, 8 A.M. serum cortisol on post-op day 1
9. imaging: (this is one paradigm, but is not standard of care)
   a) non-contrast CT scan of the brain within 6-12 hours of surgery to look for acute complications (hematoma, hydrocephalus, pneumocephalus…)
   b) pituitary-MRI without and with contrast within 72 hours of surgery to assess degree of tumor removal
10. nasal packs (if used for transspheonidal approach): remove on post-op day 3–6

Urinary output: patterns of postoperative diabetes insipidus

Manage diabetes insipidus (DI) as described above in post-op orders. Post-op DI generally follows one of three patterns[16]; see Diabetes insipidus for details (p. 124):

a) transient DI: lasts until ≈ 12–36 hrs post-op then normalizes
b) "prolonged" DI: lasts months, or rarely may be permanent
c) "**triphasic** response" (least common). 3 stages:
   1. DI (short duration): due to injury to posterior pituitary
   2. normalization or SIADH-like picture: due to release of ADH from neuron endings form hypothalamus. It is during this phase that there is a risk of severe iatrogenic hyponatremia from overtreatment initiated during the initial DI phase
   3. DI (long-term)

Discontinuation of steroids post-op

Simple management schemes

Options:

- taper and stop hydrocortisone 24–48 hrs post-op. Then, check 6 AM serum cortisol level 24 hrs after discontinuing hydrocortisone and interpret the results as shown in ► Table 54.1.[17]
- if there is any question about reserve, the patient can be discharged on hydrocortisone 50 mg PO q AM and 25 mg PO q 4 PM until adrenal reserve can be formally assessed (p. 902)

Table 54.1 Interpretation of 6 AM cortisol levels

6 AM cortisol	Interpretation	Management
≥ 9 mcg/dl	normal	no further tests or treatment
3–9 mcg/dl	possible ACTH deficiency	place patient on hydrocortisone[a] (p. 154)
≤ 3 mcg/dl	ACTH deficient	

[a] perform cosyntropin stimulation test (p. 880) 1 month post-op; D/C steroids if normal; if subnormal, then permanent replacement required

Assessment of postoperative ACTH (corticotropin) reserve

Simple assessment protocol for patients who go home on hydrocortisone and were not on it pre-op.

- taper hydrocortisone over 2–3 weeks down to 20 mg PO q AM and 10 mg q 4 PM (a little higher than maintenance to provide for some stress coverage) for several days
- then hold the PM dose and check an 8 AM serum cortisol the next day
- to avoid adrenal insufficiency in patients with incompetent reserve: as soon as the blood is drawn have the patient take their morning cortisol dose and resume regular dosing until the test results are available
- if this 8 AM cortisol shows any significant adrenal function, then taper the patient off hydrocortisone

Metyrapone (Metopirone®) test

This test more accurately assesses the hypothalamic-pituitary-adrenal axis and is useful if there is suspicion of reduced reserve of pituitary ACTH production. Metyrapone inhibits 11-β-hydroxylation in the adrenal cortex, reducing production of cortisol and corticosterone with concomitant increase of serum 11-deoxycortisol precursors and its 17-OHCS metabolites which appear in the urine. In response, a normal pituitary increases ACTH production.

1. all patients should have a cosyntropin stimulation test (p. 880) first to rule out primary adrenal insufficiency .
2. ✖ do not do this test if there is known primary adrenal insufficiency.
3. ✖ do not do this test as an outpatient.
4. test protocol
   a) give 2–3 grams metyrapone PO at midnight
   b) check serum 11-deoxycortisol level the next morning
   c) a normal response is a 11-deoxycortisol level > 7 mcg/dl
   d) CAUTION: in patients with very little reserve, the reduced cortisol may provoke adrenal insufficiency (this test is safer than the higher doses used for urinary 17-OHCS testing)

Postoperative CT/MRI scan

Immediate post-op imaging is often done to rule-out complications and to assess degree of removal (see post op orders (p. 901)). After that, it is recommended to wait 3-4 months post-op for routine follow-up imaging (usually MRI) as it may take this long for the maximal height of the pituitary gland to return to its baseline position (even with total tumor removal)[18]

54.2 Outcome following transsphenoidal surgery

54.2.1 General information

In a series of 108 macroadenomas, gross total removal was unusual in tumors with > 2 cm suprasellar extension.[15]

54.2.2 Visual deficit

In cases with compression of the optic apparatus, there can be significant improvements in vision following surgery.[15,19]

54.2.3 Biochemical outcome for hormonally active tumors

Prolactinomas

In a series of 108 macroadenomas, endocrinologic cure was attained in 25% of prolactin-secreting tumors.[15]

Acromegaly

Criteria of biochemical cure

The criteria for biochemical cure of acromegaly is not standardized. There may be a discord between IGF-1 levels and mean GH levels.[20] Many use a GH cutoff level; range of levels described: < 2.5–5 ng/ml. Others feel that an elevated IGF-1 represents lack of cure even if GH < 5. However, normal IGF-1 levels may not be mandatory.[21] Still others require a normal IGF-1 AND a normal response to an oral glucose suppression test (OGST) (p. 882).

Low GH levels that do not also suppress to < 1 ng/ml after an OGST are considered controlled but not cured (even with normal IGF-1 levels).[22] If asymptomatic, expectant management with close follow-up is recommended.[22]

Σ: Biochemical cure criteria for acromegaly after treatment

Biochemical cure criteria for acromegaly is not standardized. Recommendation[22]:
1. IGF-1 levels within age-matched reference range
2. basal (morning) serum GH level < 5 ng/ml, AND GH nadir < 1 ng/ml in OGST

Outcome with acromegaly

Transsphenoidal surgery results in biochemical cure in 85% of cases with adenomas < 10 mm diameter, no evidence of local invasion, and random GH levels < 40 ng/ml pre-op. Overall, ≈ 50% of *all* acromegalics undergoing transsphenoidal surgery had a biochemical cure.[23] Only 30% of macroadenomas and very few with marked suprasellar extension have surgical cure. Patients not cured with surgery require lifelong medical suppression. These tumors may also recur years later after apparent cure. Patients should be monitored every 6–12 months for recurrence.[22]

Cushing's disease

There are numerous methodologies for determining biochemical cure for Cushing's disease. One difficulty is that exogenous steroids are often given post-op to avoid potential hypoadrenalism or Addisonian crisis or for nausea, and this can obscure the evaluation. Some options:

1. immediate post-op early morning cortisol levels[9]:
   a) all steroids are withheld post-op (including dexamethasone as an antiemetic) unless biochemical and/or clinical evidence of hypocortisolism (clinical signs: nausea, anorexia, H/A, arthralgias). ✖ Requires close monitoring and administration of steroids if symptoms develop
   b) serum ACTH and cortisol levels are drawn between 6 AM and 9 AM on post-op days 1 & 2
   c) early remission defined as a *lowest* cortisol level ≤ 140 nmol/L (≤ 5 mcg/dl)
      - 97% (31/32) patients with early remission had sustained remission with mean follow-up of 32 months
      - only 12.5% (1/8) without early remission showed evidence of sustained remission
      - this has been used to select patients for possible early re-exploration
      - early ACTH levels usually drop, but do not consistently become subnormal and are not reliable in predicting sustained remission[9]
2. provocative tests
   a) overnight low-dose dexamethasone suppression test: an AM cortisol level on post-op day 3 that is ≤ 8 mcg/dl after an overnight 1 mg dexamethasone suppression test is predictive of sustained remission in 97%[24]
   b) CRH stimulation test[25]
3. measurements usually conducted 3 days to 2 weeks post-op following 24 hours of steroid cessation after initial post-op coverage with glucocorticoids
   a) 24-hour urinary free cortisol
   b) serum cortisol: the criteria of a cortisol level < 50 nmol/l (< 1.8 mcg/dl)[26,27,28] is probably too stringent[9,29,30]
   c) serum ACTH

The overall remission rate since 1980 is 64–93%, with the highest rates (86–98%) in patients with noninvasive microadenomas identifiable on MRI.[9]

Following effective treatment, all of the following usually improve but may not normalize:

1. HTN and hyperglycemia: within ≈ 1 year
2. osteoporosis related to CD: over ≈ 2 years
3. psychiatric symptoms

Thyrotropin (TSH)-secreting adenomas

Following debulking, small amounts of residual tumor may continue to produce sufficient TSH for hyperthyroidism to persist.[31] Following surgery + XRT, only ≈ 40% achieve a cure (defined as no residual tumor at surgery or on imaging, and normal free T3 with TSH levels at or below normal).

54.3 Follow-up suggestions for PitNET/adenomas

54.3.1 Nonfunctioning PitNET/adenomas

Post treatment follow-up

Due to the lack of active hormonal products that can be followed with serial lab tests, follow-up relies primarily on serial imaging and monitoring for signs of mass effect from growing tumors (e.g., increasing visual field defects).

Practice guideline: Posttreatment follow-up evaluation for nonfunctioning PitNET/adenomas

Radiologic follow-up

Level III[32]

1. T1WI fat sat & T2WI MRI should be included in imaging of NFPAs after surgery or XRT
2. long-term surveillance for tumor regrowth or recurrence is recommended
3. patients with radiologically-proven gross total resection of NFPA require less frequent monitoring than those with subtotal resection
4. the first post-op imaging should be obtained 3–4 months post-op

Level inconclusive recommendations[32]

1. there is insufficient evidence to make recommendations for frequency of imaging or length of surveillance after surgery or XRT for NFPAs
2. there is insufficient evidence to make recommendations for the timing of the first post-XRT imaging

Endocrinologic follow-up

Level III[32]

1. evaluation for endocrinologic pituitary dysfunction is recommended after surgery and/or XRT for NFPAs
2. post-op adrenal function evaluation is recommended on post-op day 2, week 6, and 12 months
3. perioperative corticosteroid supplementation is recommended for patients with hypocortisolemia pre-op or on post-op day 2
4. post-op endocrinologic follow-up is not recommended beyond 1 year in patients with normal pituitary function
5. endocrinologic follow-up after surgical resection of NFPAs is recommended indefinitely in patients with abnormal pituitary function or those who undergo XRT of NFPAs
6. surveillance of serum sodium for 48 hours after surgery and on post-op days 7–8 is recommended to avoid symptomatic post-op hyponatremia

Level inconclusive recommendations[32]

1. there is insufficient information to make recommendations on the detection and treatment of post-op diabetes insipidus (DI)
2. there is insufficient evidence to make recommendations for frequency of endocrinologic evaluation after surgery or XRT for NFPAs

Ophthalmologic follow-up

Level III[32]

- ophthalmologic follow-up to assess visual fields and acuity is recommended after surgery and/or XRT for NFPAs

Level inconclusive recommendations[32]

- there is insufficient evidence to make recommendations on the frequency or duration of ophthalmologic follow-up

Integrated follow-up

Level inconclusive recommendations[32]

- there is insufficient evidence to make recommendations on integration of imaging, endocrinologic and ophthalmologic follow-up after surgery or XRT for NFPAs

54.4 Recurrent PitNET/adenomas

Recurrence incidence: ≈ 12%, with most recurring 4–8 years post-op (in the same series[15]).

For tumors demonstrating significant regrowth or symptoms following initial resection, consideration for re-resection may be given. Once the tumor is debulked, consideration should be given to XRT, either immediately following the second operation, or, if recurrence after a second operation then almost certainly after a third debulking.

55 Metastases to the CNS

55.1 Cerebral metastases

55.1.1 General information

Key concepts

- brain metastases are the most common brain tumor seen clinically
- at the time of onset of neurologic symptoms, 70% will be multiple on MRI
- with solitary brain lesions in a patient with a history of cancer, biopsy should almost always be done since 11% of these lesions will not be mets
- although median survival with maximal treatment is only 8 months (similar to GBM), long-term survivors do occur

55.1.2 Metastases to the brain

Cerebral metastases are the most common brain tumor seen clinically, comprising slightly more than half of brain tumors (if one considers only imaging studies, they comprise ≈ 30%). In the U.S., the annual incidence of new cases of metastases is up to 170,000,[1] compared to 17,000 for primary brain tumors. 15–30% of patients with cancer (Ca) develop cerebral mets.[2] In patients with no Ca history, a cerebral met was the presenting symptom in 15%; of these, 43–60% will have an abnormal chest X-ray (**CXR**)[3,4] (showing either a bronchogenic primary or other mets to lung).

In 9% of cases, a cerebral met is the only detectable site of spread. Cerebral mets occur in only 6% of pediatric cancers.

The route of metastatic spread to the brain is usually hematogenous, although local extension can also occur.

Solitary mets

- CT (p. 914): at the time of *neurologic* diagnosis, 50% are solitary on CT[5,6]
- MRI: if the same patients have an MRI, < 30% will be solitary[7]
- on autopsy: mets are solitary in one–third of patients with brain mets, and 1–3% of solitary mets occur in the brainstem[8]

Increasing incidence of cerebral mets: may be due to a number of factors including:

1. increasing length of survival of cancer patients[9] as a result of improvements in treatment of systemic cancer
2. enhanced ability to diagnose CNS tumors due to availability of CT and/or MRI
3. many chemotherapeutic agents used systemically do not cross the blood-brain barrier (BBB) well, providing a “haven” for tumor growth there
4. some chemotherapeutic agents may transiently weaken the BBB and allow CNS seeding with tumor

55.1.3 Metastases of primary CNS tumors

Spread via CSF pathways

CNS tumors that more commonly spread via CSF pathways include the following (when these tumors spread to the spinal cord, they are often called “drop mets”):

1. high grade gliomas (p. 667) (10–25%)
2. embryonal tumors, primarily medulloblastoma (p. 750)
3. ependymoma (p. 724) (11%)
4. choroid plexus tumors (p. 739)
5. pineal region tumors
   a) germ cell tumors (p. 831)
   b) pineocytoma (p. 762) and pineoblastoma (p. 764)
6. rarely:
   a) oligodendrogliomas (p. 662) (≈ 1%)

b) hemangioblastomas (p. 822)
c) primary CNS melanoma (p. 830)

Extraneural spread

Although most CNS tumors do not spread systemically, there is some potential for extraneural spread with the following tumors:

1. medulloblastoma: the most common primary responsible for extraneural spread. May spread to lung, bone marrow, lymph nodes, abdomen
2. meningioma: rarely goes to heart or lungs
3. malignant astrocytomas rarely metastasize systemically
4. ependymomas
5. pineoblastomas
6. meningeal sarcomas
7. choroid plexus tumors
8. tumors that spread through CSF pathways (see above) may spread via a CSF shunt (e.g., to peritoneum with VP shunt or hematogenously with a VA shunt); however, this risk is probably quite small[10]

55.1.4 Location of cerebral mets

Intracranial metastases may be either parenchymal (≈ 75%) or may involve the leptomeninges in a carcinomatous meningitis (p. 920). 80% of solitary metastases are located in the cerebral hemispheres.

The highest incidence of parenchymal mets is posterior to the Sylvian fissure near the junction of temporal, parietal, and occipital lobes (presumably due to embolic spread to terminal MCA branches).[11] Many tend to arise at the gray/white-matter interface.

The cerebellum is a common site of intracranial mets, and is the location in 16% of cases of solitary brain mets. It is the most common p-fossa tumor in adults, thus "a solitary lesion in the posterior fossa of an adult is considered a metastasis until proven otherwise." Spread to the posterior fossa may be via the spinal epidural venous plexus (Batson's plexus) and the vertebral veins.

55.1.5 Primary cancers in patients with cerebral metastases

General information

Accurately ascertaining the source of cerebral metastases in the U.S. is difficult because of lack of detailed coding.[12] In over 2,700 adults with a primary cancer undergoing autopsy at Sloan-Kettering, the sources of cerebral metastases are shown in ▶ Table 55.1. Sources of brain metastases in pediatrics is shown in ▶ Table 55.2.

In adults, lung and breast Ca together account for > 50% of cerebral mets.

Table 55.1 Sources of cerebral mets in adults (autopsy data)

Primary	%
lung Ca	44
breast	10
kidney (renal cell)[a]	7
GI (colorectal)	6
melanoma[b]	3
undetermined	10

[a] an uncommon tumor that metastasizes frequently to brain (in 20–25% of cases)
[b] 16% in older series[13]

Table 55.2 Sources of cerebral mets in peds

neuroblastoma
rhabdomyosarcoma
Wilm's tumor

In patients with a metastatic brain tumor as the initial presentation (i.e., undiagnosed primary) in 5-10% of cancers, and compared to patients with a known primary, there is about the same number of brain lesions, but there was an increased frequency of extracranial mets.[14] In up to 26% of cases, the primary tumor was never identified.[14]

The autopsy incidence of cerebral mets for various types of primary cancers at Sloan-Kettering Cancer Center is shown in ▶ Table 55.3.

Table 55.3 Autopsy incidence of cerebral mets for given primary cancers

Primary	% with cerebral mets
lung	21
breast	9
melanoma	40
lymphoma	1
• Hodgkin's	0
• non-Hodgkin's	2
GI	3
• colon	5
• gastric	0
• pancreatic	2
GU	11
• kidney (renal)	21
• prostate[a]	0
• testes	46
• cervix	5
• ovary	5
osteosarcoma	10
neuroblastoma	5
head and neck	6

[a] uncommon, but does occur

Lung cancer

The lungs are the most common source of cerebral mets, and these are usually multiple. The lung primary may be so small as to render it occult.

Necropsy demonstrates cerebral mets in up to 50% of patients with small-cell lung Ca (SCLC) and non-squamous, non-small-cell lung Ca.[15]

Cigarette smoking is responsible for 88% of all types of lung cancer combined (odds ratio for developing any type of lung cancer with cigarette smoking is 13.4), 91% of squamous cell (OR = 18.8), 89% of small cell (OR = 14.3), 95% of large cell (OR =34.3), and 82% of adenocarcinoma (OR = 7.9).[16]

Small-cell lung cancer (SCLC)

AKA "oat cell" Ca. A neuroendocrine tumor. 95% arise in proximal airways, usually in mainstem or lobar bronchi. Typically younger (27–66 years) than other lung Ca. Median survival: 6–10 months. Considered a systemic disease. Staged in 1 of 2 categories:

1. limited: confined to an area of the chest that can be encompassed by a single radiation port
2. extensive: metastasis outside the thorax or intrathoracic disease that cannot be contained in a single radiation port

Although SCLC comprises only ≈ 20% of primary lung cancers, it is more likely to produce cerebral mets than other bronchogenic cell types (brain mets are found in 80% of patients who survive 2 yrs after diagnosis of SCLC).[9]

Treatment

Very radiosensitive.

No identified brain mets: prophylactic cranial irradiation (PCI) with WBXRT reduces the incidence of symptomatic brain mets and increases survival (disease-free & overall).[17,18] Typically 25 Gy in 10 fractions.

Brain mets: surgical resection considered for immediately life-threatening large lesions, XRT is used otherwise. Multiple SCLC brain lesions: XRT (initial treatment 30 Gy in 10 fractions) + chemotherapy.

Treatment of primary: usually not resected. Treated with chemotherapy ± XRT.

Recurrent brain mets after failure of initial treatment: 20 Gy in 10 fractions.

Non-small-cell lung cancer (NSCLC)

Includes: adenocarcinoma (the most common NSCLC), large cell, squamous cell, bronchoalveolar. Retrospective analysis of patients with NSCLC completely resected from the lung found a 6.8% first recurrence rate in the brain.[15] Staged with typical TNM system. Prognosis better than SCLC.

Treatment of lung primary:

1. grades I, II, IIIA: resection
2. higher grades (e.g., distal mets, excluding single brain met): XRT + chemotherapy

Staging studies for known lung primary

1. PET scan: can detect small malignancies. Useful in NSCLC to determine eligibility of resection of primary. Not useful in initial evaluation of SCLC
2. chest CT: usually includes adrenals and liver (thus abdomen and pelvis CT not necessary)
3. bone scan
4. brain: CT or MRI

When metastatic lung cancer is the suspected source of a newly diagnosed brain lesion, the lung lesion should be biopsied (if technically feasible) to rule out SCLC before obtaining tissue from the cerebral mass because XRT is the primary treatment for SCLC brain metastases.

Melanoma

General information

Melanoma: the 5th most common cancer in men, 7th in women. Incidence is increasing. Most common sites of origin of melanoma metastases: skin, retina, brain—primary CNS melanoma (p. 830)—nail bed. The primary site cannot be identified in up to ≈ 14% of cases.[19] Extremely difficult to locate primary sites: intraocular, GI mucosa.

Brain mets are found in 10–70% of patients with metastatic melanoma in clinical studies, and in 70–90% on autopsy of patients who died from melanoma. Patients with melanoma who have neurosurgical lesions typically presented 14 months after primary lesion was identified. Once cerebral mets of melanoma are detected, median survival is ≤ 6 months[20,21,22] and the mets contributed to the death in 94% of cases.[23] A small group with survival > 3 yrs had a single surgically treated met in the absence of other visceral lesions.

Evaluation

Metastatic melanoma to the brain classically causes pia/arachnoid involvement on imaging. Hemorrhagic involvement is common.

CT: lesions may be slightly hyperdense to brain on unenhanced CT due to melanin. Enhancement is less constant than for other mets (e.g., bronchogenic Ca).

MRI: decreased signal on T2WI surrounded by intense halo of edema. Enhancing T1WI lesions in a patient with melanoma is highly suggestive of melanoma metastases.

Systemic work-up: systemic disease determines ultimate survival after treatment of melanoma mets to the brain in 70% of patients. ∴ search for systemic mets should be done, including: CT of chest/abdomen/pelvis & bone scan. PET scan may be more sensitive for detecting metastatic spread than CT when there are clinical signs that the tumor has spread[24]; *except for the brain*, where brain MRI is more sensitive than CT or PET.

Treatment

Suggested algorithm for patients with metastatic melanoma to the brain (adapted,[25] see ▶ Fig. 55.1).

Patients with **Karnofsky performance scale (KPS) score** (p. 1640) **< 70** are likely to be poor surgical candidates.

Fig. 55.1 Suggested algorithm for patients with metastatic melanoma to the brain (adapted[25]). Abbreviations: BRAFi = BRAF inhibitors, SRS = stereotactic radiosurgery (p. 1903), WBRT = whole brain radiation therapy.

Some key points:

1. patients with rapidly progressive systemic disease: treat the systemic disease with chemotherapy first, before dealing with the brain mets
2. patients without systemic disease and 1–4 mets are candidates for surgery if all mets are accessible and can all be removed[26] (this is a general principle for brain mets, not just for melanoma). SRS is an alternative

► **Surgical indications**

1. patients with 1–4 CNS metastases that can be completely resected when systemic disease is absent or slowly progressive: long-term survival is possible
2. patients with intracranial mets that cannot be completely removed or with uncontrolled systemic disease may be surgical candidates for the following:
   a) for symptomatic relief: e.g., lesion causing painful pressure
   b) life-threatening lesion: e.g., large p-fossa lesion with 4th ventricle compression
   c) for hemorrhagic lesion causing symptoms by mass effect from the clot

► **Whole-brain radiation therapy (WBRT).** Melanoma is typically radioresistant. WBRT provides 2–3 month survival benefit and may be considered for palliation in patients with multiple mets that preclude complete excision or SRS.

► **Stereotactic radiosurgery (SRS).** Considered for ≤ 4 lesions, all ≤ 3 cm in diameter, that are surgically inaccessible, with limited or quiescent systemic involvement. Relative contraindications: hemorrhagic lesions, lesions with significant mass effect surrounding edema.

▶ **Chemotherapy**

1. alkylating agents:
   a) dacarbazine, formerly the gold-standard treatment for melanoma. About equally as effective as its newer orally administered analog temozolomide (Temodar®). Response rate: 10–20%
   b) Fotemustine appeared promising in phase II trials but only 6% responded in phase III (vs. 0% for dacarbazine)[27]
2. immunotherapy:
   a) ipilimumab (Yervoy®): monoclonal antibody against cytotoxic T lymphocyte antigen-4 (CTLA-4) antigen. More effective in patients who do not require corticosteroids
   b) interleukin-2 (IL-2): has shown minimal activity in brain mets, and trials have usually excluded patients with untreated or uncontrolled brain mets due to risk of cerebral edema and hemorrhage from capillary leak[28,29,30]
3. BRAF inhibitors (BRAFi): inhibits BRAF kinase (a protein that participates in regulation of cell division and differentiation), useful in tumors with BRAF oncogene mutation (as opposed to BRAF wildtype) which is common in melanoma
   a) dabrafenib: phase II trial (NCT01266967)[31]
   b) vemurafenib: promising results in heavily treated patients. Phase II trial (NCT01378975)[32]
4. anti-PD-1 drug (monoclonal antibody to PD-1 programmed cell death receptor): pembrolizumab (Keytruda) approved for advanced or unresectable melanoma not responding to other drugs[33]

Outcome

1. in a patient with a single brain met (any type) and good Karnofsky performance score (> 70) and no evidence of extracranial disease, surgery + XRT had a median survival of 40 weeks vs. 15 weeks for XRT alone[34,35]
2. for melanoma, retrospective studies have shown a benefit of treatment with either surgery or SRS only when all brain lesions are completely treated (selection bias possible in these studies)[35,36,37,38]
3. predictors of poor outcome in melanoma:
   a) > 3 brain mets[21]
   b) development of brain mets after the diagnosis of extracranial disease[21]
   c) elevated lactate dehydrogenase > 2 × normal[22]
   d) presence of bone metastases[22]
   e) multiple brain mets and extensive visceral disease[39]

Renal-cell carcinoma

AKA hypernephroma. Usually associated with spread to lungs, lymph nodes, liver, bone (high affinity for bone), adrenals, and contralateral kidney before invading the CNS (thus, this tumor rarely presents as isolated cerebral metastases). Look for hematuria, abdominal pain, and/or abdominal mass on palpation or CT. Response to XRT is only ≈ 10%.

Esophageal cancer

Median survival is 4.2 months based on a review of 26 cases.[40] Solitary brain met with good Karnofsky score and surgical treatment may indicate a better prognosis.

55.1.6 Clinical presentation

As with most brain tumors, signs and symptoms are usually slowly progressive compared to those from vascular events (ischemic or hemorrhagic infarcts), which tend to be sudden in onset and slowly resolve, or electrical events (seizures), which tend to be sudden in onset and rapidly resolve. Metastases may also present acutely by hemorrhaging, causing an intraparenchymal hematoma (IPH). There are no findings that would allow differentiation of a metastatic tumor from a primary neoplasm on clinical grounds.

Signs and symptoms include:

1. those due to increased ICP from mass effect and/or blockage of CSF drainage (hydrocephalus):
   a) headache (H/A): the most common presenting symptom, occurs in ≈ 50%
   b) nausea/vomiting
2. focal deficits:
   a) due to compression of brain parenchyma by mass and/or peritumoral edema (e.g., monoparesis without sensory disturbance)
   b) due to compression of cranial nerve

3. seizures: occur only in ≈ 15% of cases
4. mental status changes: depression, lethargy, apathy, confusion
5. hemorrhage (p. 1612): producing IPH, often with H/A and sudden onset of focal deficit, obtundation may occur with large hemorrhages
6. symptoms suggestive of a TIA (dubbed "tumor TIA") or stroke, may be due to:
   a) occlusion of a vessel by tumor cells
   b) hemorrhage into the tumor, especially common with metastatic melanoma, choriocarcinoma, and renal-cell carcinoma[41]; see Hemorrhagic brain tumors (p. 1612). May also occur due to decreased platelet count

55.1.7 Evaluation

Imaging studies (CT or MRI)

Metastases usually appear as "non-complicated" masses (i.e., round, well circumscribed), often arising at the gray/white junction (▶ Fig. 55.2). Characteristically, profound white matter edema ("fingers of edema") reach deep into the brain from the tumor, usually more pronounced than that seen with primary (infiltrating) brain tumors. When multiple lesions are present (on CT or MRI of brains with multiple mets) Chamber's rule applies: "Whoever counts the most mets is right." Mets usually enhance, and must be considered in the differential diagnosis of a ring-enhancing lesion.

MRI is more sensitive than CT, especially in the posterior-fossa (including brain stem). Detects multiple mets in up to ≈ 20% of patients who appear to have single mets on CT.[2]

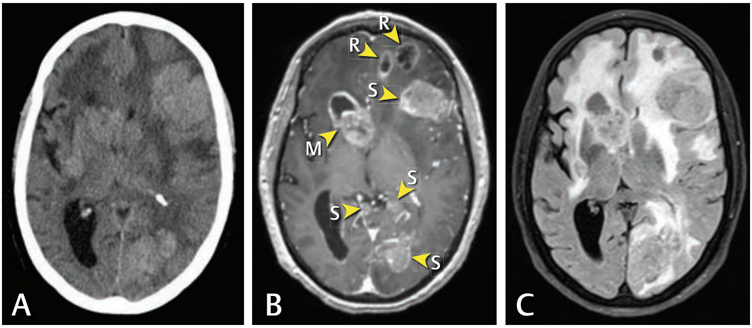

Fig. 55.2 Cerebral metastases.
65-year-old woman with small cell cancer of the lung metastatic to the brain.
Image: A: axial non-contrast head CT obtained at admission. B: axial MRI T1 + contrast, showing multiple metastatic lesions (*yellow arrowheads*) (which were also present in the cerebellum, not shown), some are solid (S), some are ring enhancing (R), and some are mixed (M). C: axial T2 MRI demonstrating characteristic extensive white-matter "fingers of edema."

Lumbar puncture

Relatively contraindicated when there is a cerebral mass (may be considered once mass lesion has been ruled out). May be most useful in diagnosing carcinomatous meningitis (p. 920), and may be of limited help in diagnosing CNS lymphoma.

Metastatic work-up with suspected brain metastases

When metastatic disease is suspected based on imaging, a search for a primary site and assessment for other metastatic lesions may be considered since it may provide alternative sites for tissue for histologic diagnosis, and it may guide treatment (e.g., widely disseminated metastases may preclude aggressive therapy). It is also undertaken to look for a primary and other metastases when biospy is consistent with brain metastases.

Metastatic work-up should include:

1. CT of the chest (more sensitive than CXR), abdomen and pelvis. Evaluates for primary and additional mets (to lung, adrenals, liver... CT has superseded CXR)
2. radionuclide bone scan: for patients with bone pain or bone lesions or for tumors that tend to produce osseous metastases (especially: prostate, breast, kidney, thyroid & lung)
3. mammogram in women
4. prostate specific antigen (PSA) in men
5. PET scan: can detect small malignancies

Cancer of unknown primary site (CUP): If the metastatic work-up (see above) is negative, the pathology of a metastatic brain lesion as determined by biopsy may implicate specific primary sites.

Small-cell carcinoma metastatic to the brain is most likely from the lung. These tumors stain positive for neuroendocrine stains (p. 632).

Adenocarcinoma: lung is the most common primary. Other sources: GI (mostly colon), breast. The primary site may remain occult even after extensive evaluation in up to 88%.[42] Immunostaining has been tried to identify the primary site but has not been found to be widely useful.

55.1.8 Management

General information

With optimal treatment, median survival of patients with cerebral mets is still only ≈ 26–32 weeks, therefore management is mostly palliative. Also see Outcome (p. 919) for comparison of various treatments.

Confirming the diagnosis

NB: 11% of patients with abnormalities on brain CT or MRI with a history of cancer (within past 5 yrs) do not have cerebral metastases.[34] Differential diagnoses include: primary brain tumor (glioblastoma, low grade astrocytoma), abscess, and nonspecific inflammatory reaction. If non-surgical treatment (e.g., chemotherapy or XRT) is being contemplated, the diagnosis should first be confirmed by biopsy in almost all cases.

Management decisions

Prognostication

This is critical since many treatment decisions depend on overall prognosis.

RTOG RPA: Radiation Therapy Oncology Group recursive partitioning analysis classification[43] (see ▶ Table 55.4). Conclusion: the specific tumor type, length of time since diagnosis, etc. are not as important prognostically as the Karnofsky Performance Scale (KPS) score (p. 1640).

The applicability of RPA to melanoma mets to the brain is controversial (it has been both validated[44] and disputed[38]).

RPA Class 3 patients have been shown to be unlikely to benefit from any of numerous treatment modalities studied. Class 1 are more likely to benefit. Most patients are Class 2, for whom benefit is unclear.

55

Table 55.4 Radiation Therapy Oncology Group recursive partitioning analysis (RPA) classification for patients with brain mets (from 1200 patients with ≥ 1 brain mets undergoing XRT)[43]

RPA class	Description	Median survival (mos)[a]
1	• KPS[b] ≥ 70 and • age < 65 years and • controlled[c] or absent primary tumor with the brain the only site of metastasis	7
2	• all others (i.e., not RPA class 1 or 3)	4
3	• KPS < 70	2

[a] for patients undergoing XRT
[b] KPS = Karnofsky Performance Scale score (p. 1640)
[c] controlled = stable disease over 3 months observation

Management algorithm

▶ Table 55.5 shows a summary of management suggestions (details appear in following sections).

Also, surgical excision may be considered for patients with completely resectable brain mets who are candidates for chemotherapy with interleukin-2 (IL-2) for systemic disease (e.g., for renal-cell Ca or melanoma) since there are case reports of significant cerebral edema associated with use of this drug in the presence of cerebral mets.

Table 55.5 Management suggestions for cerebral metastases[a]

Clinical situation		Management
unknown primary or unconfirmed diagnosis		stereotactic biopsy for ≈ all patients if surgical excision is not a consideration
uncontrolled widespread systemic cancer & obviously short life expectancy and/or poor performance status, KPS (p. 1640) ≤ 70		(biopsy as indicated above) + WBXRT or no treatment
metastases known to be extremely radiosensitive (lymphoma, small cell lung cancer, germ cell tumor, multiple myeloma)		XRT
Stable systemic disease & KPS > 70		
solitary met	symptomatic or threatening, and safely resectable[b] lesion	surgical excision[c, d] + WBXRT[e] or surgical excision[c, d] + SRS[e]
	asymptomatic, small, or not safely resectable[b]	WBXRT ± SRS boost
multiple mets	single large lesion that is life threatening or producing mass effect	surgery for the large lesion + WBXRT for the rest
	≤ 3 lesions: symptomatic & can all be removed	surgery + WBXRT or SRS + WBXRT
	≤ 3 lesions: cannot all be removed	WBXRT or SRS + WBXRT
	> 3 lesions: with no mass effect requiring surgery	WBXRT[45]

[a] adapted Pollock et al.[46] and the 2019 Congress of Neurological Surgeons Systematic Review and Evidence-Based Guidelines[47,48]

[b] safely resectable lesion implies surgery can be performed without undue risk of worsening neurologic condition (including hemiparesis, aphasia…) that would lower KPS and thereby shorten longevity

[c] surgery + WBXRT is superior to WBXRT alone (Level 1); surgery + SRS is superior to SRS alone (Level 3)[47]

[d] surgical excision: class III data suggests gross total resection is superior to subtotal resection in RPA class I patients, and that with single mets that en bloc resection reduses the risk of leptomeningeal disease compared to piecemeal resection[47]

[e] NB: used alone for patients with 1-3 mets, SRS is better for survival and neurocognition but is worse for local and distant control compared to WBXRT

Abbreviations: KPS = Karnofsky Performance Scale score (p. 1640); SRS = stereotactic radiosurgery; WBXRT = whole brain radiation therapy.

Medical management

Initial treatment

1. **antiseizure medications**: e.g., Keppra® (levetiracetam) starting with 500 mg PO or IV q 12 hours. Generally not indicated for posterior fossa lesions due to low epileptogenicity with these. Guidelines: ASMs showed a nonstatistically significant reduction of early seizures, and had no benefit for seizures at 3 months or for survival.[49,50]Guideline conclusions: no compelling data for prophylactic ASM pre-op or post-op.
   Non-guideline opinion: use is more justifiable in patients who actually have a seizure
2. corticosteroids: many symptoms are due to peritumoral edema (which is primarily vasogenic), and respond to steroids within 24–48 hrs. This improvement is not permanent, and prolonged steroid administration may produce side effects; see Possible deleterious side effects of steroids (p. 626).
   Guidelines: steroids are recommended for temporary relief of symptoms due to increased ICP or edema related to mets (Level 3).[51] There is insufficient evidence to make recommendations for use with asymptomatic lesions without mass effect.[51]

Dexamethasone is the drug of choice (Level 3)[51]
℞ for mild-to-moderate symtoms in a patient who is not already on steroids: dexamethasone (Decadron®) 4-8 mg/d (Level 3)[51] usually given in divided doses. Higher doses are not more effective and side effects are more common[52]
℞ for severe symptoms consider higher dose of 16 mg/d (Level 3).[51]
Regardless of regimen used, taper steroids as rapidly as tolerated to the lowest effective dose for symptom control(Level 3).[51]

3. H2 antagonists (e.g., ranitidine 150 mg PO q 12 hrs) or proton pump inhibitor (omeprazole)

Chemotherapy

See discussion of Limitations of chemotherapy in the brain (p. 627). If multiple lesions of known small-cell Ca are detected on cerebral imaging, treatment of choice is radiation plus chemotherapy.

Radiation therapy

General information

NB: not all brain lesions in cancer patients are mets (see above).

In patients not considered for surgery, steroids and radiation may be palliative. H/A are usually reduced, and in ≈ 50% of cases symptoms improve or completely resolve.[53] This does not result in local control for the majority of these patients and they frequently succumb from progressive brain disease.

"Radiosensitivity" of various metastatic tumors to whole brain radiation therapy (WBXRT) are shown in ▶ Table 55.6.

The usual dose is 30 Gy in 10 fractions given over 2 weeks. With this dose, 11% of 1-yr survivors and 50% of 2-yr survivors develop severe dementia.

Table 55.6 "Radiosensitivity" of brain metastases to WBXRT

Radiosensitivity	Tumor
Radiosensitive[34]	• small-cell lung Ca • germ cell tumors • lymphoma • leukemia • multiple myeloma
Moderately sensitive	• breast
Moderately resistant	• colon • non small-cell lung cancer
Highly resistant[a]	• thyroid • renal cell (10% respond) • malignant melanoma • sarcoma • adenocarcinoma

[a] SRS may be better than WBXRT for these

Prophylactic cranial irradiation

Prophylactic cranial irradiation after resection of small-cell lung carcinoma (SCLC) reduces relapses in brain, but does not affect survival.[54]

Post-op radiation therapy

WBXRT is usually recommended following craniotomy for metastatic disease,[55] especially with SCLC where "micro-metastases" are presumed to be present throughout brain. (**Note:** some centers do not routinely administer post-op WBXRT (except for very radiosensitive tumors such as SCLC) but instead follow patients with serial imaging studies and administer XRT only when metastases are documented.)

Optimal dose is controversial. Early reports recommended 30–39 Gy over 2–2.5 weeks (3 Gy fractions) with or without surgery.[56] This is acceptable in patients not expected to live long enough to get long-term radiation effects. Recent recommendations are for smaller daily fractions of 1.8–2.0 Gy to reduce neurotoxicity.[57] These low doses are also associated with a higher rate of recurrent brain metastases.[58] Since 50 Gy are needed to achieve > 90% control of micrometastases, some use

45–50 Gy WBXRT, plus a boost to the tumor bed to bring the total treatment up to 55 Gy, all with low fractions of 1.80–2.0 Gy.[59]

Stereotactic radiosurgery

Inconsistent in its ability to reduce tumor size. Some retrospective studies show results comparable to surgery.[60] Others do not.[61] Does not obtain tissue for histological analysis, and generally cannot be used for lesions > 3 cm. Also, see Stereotactic radiosurgery (p. 919).

Surgical management

Solitary lesions

Indications favoring surgical excision of a solitary lesion:

1. primary disease quiescent
2. lesion accessible
3. lesion is symptomatic or life-threatening
4. primary tumor known to be relatively radioresistant (excision is rarely indicated for untreated brain metastases from SCLC because of its radiosensitivity)
5. for recurrent SCLC following XRT
6. diagnosis unknown: alternatively consider biopsy, e.g., stereotactic biopsy

Surgical resection in patients with progressive systemic disease and/or significant neurologic deficit is probably unjustified.[62] Also, in newly diagnosed cancer patients, craniotomy may delay systemic treatment for weeks and the ramifications of this need to be considered.

Multiple lesions

Patients with multiple metastases generally have much worse survival than those with solitary lesions.[57] Multiple metastases are usually treated with XRT without surgery. However, if total excision of *all* mets is feasible, then even multiple mets may be removed with survival similar to those having a single met removed[26] (also see ► Table 55.5 for summary). If only incomplete excision is possible (i.e., cannot remove all mets, or portions of 1 or more must be left behind) then there is no improvement in survival with surgery, and XRT alone is recommended. The mortality of removing > 1 met at a single sitting is not statistically significantly higher than removing a single met.

Situations where surgery may be indicated for multiple mets[63]:

1. one particular and accessible lesion is clearly symptomatic and/or life threatening (life-threatening lesions include p-fossa and large temporal lobe lesions). This is palliative treatment to reduce the symptom/threat from that particular lesion
2. multiple lesions that can all be completely removed (see above)
3. no diagnosis (e.g., no identifiable primary): consider stereotactic biopsy

Stereotactic biopsy

Considered for:

1. lesions not appropriate for open surgery. Includes cases with no definite diagnosis and:
   a) deep lesions
   b) multiple small lesions
2. patients not candidates for surgical resection
   a) poor medical condition
   b) poor neurologic condition
   c) active or widespread systemic disease
3. to ascertain a diagnosis
   a) when another diagnosis is possible: e.g., no other sites of metastases, long interval between primary cancer and detection of brain mets…
   b) especially if nonsurgical treatment modalities are planned (see above)

Intraoperative considerations for surgical removal

Most lesions present themselves on the surface of the brain or through the dura. For lesions not visible on the surface nor palpable immediately beneath the surface, intraoperative ultrasound or stereotactic techniques may be used to localize the lesion.

Metastases usually have a well defined border, thus a plane of separation from normal brain may be exploited, often allowing gross total removal.

55.1.9 Outcome

General information

▶ Table 55.7 lists factors associated with better survival regardless of treatment. Also, the prognosis gets worse as the number of mets increases.[46] Median survival even with best treatment in some studies is only ≈ 6 months. To put this into perspective, this is worse than with glioblastoma.

Table 55.7 Factors associated with better prognosis for brain mets (with any treatment)

• Karnofsky score[a] (KPS) > 70 • age < 60 yrs • metastases to brain only (no systemic mets) • absent or controlled primary disease • > 1 yr since diagnosis of primary • the fewer the number of brain mets • female gender
[a]the KPS (p. 1640) is probably the most important predictor; those with a score of 100 had median survival > 150 weeks

Natural history

By the time that neurologic findings develop, median survival among untreated patients is ≈ 1 month.[64]

Steroids

Using steroids alone (to control edema) doubles survival[65] to 2 mos (**Note:** this is based largely on pre-CT era data, and the tumors were therefore probably larger than in current studies[66]).

Whole brain radiation therapy (WBXRT)

WBXRT + steroids increases survival to 3–6 mos.[26] 50% of deaths are due to progression of intracranial disease.

Surgery ± WBXRT

Recurrence of tumor was significantly less frequent and more delayed with the use of post-op WBXRT.[55] Length of survival was unchanged with supplemental use of WBXRT. There is also an additional loss of cognitive function in many cases, and patients are rarely independent after WBXRT.

In 33 patients treated with surgical resection of single mets and post-op WBXRT[67]: median survival was 8 months; with 44% 1-yr survival. If no evidence of systemic Ca, 1-yr survival is 81%. If systemic Ca is present (active or inactive), 1-yr survival is 20%. Patients with solitary mets and no evidence of active systemic tumor have the best prognosis.[53,62] With total removal, no recurrence nor new parenchymal mets occurred within 6 months, and the major cause of death was progression of Ca outside the CNS. A randomized trial verified the improved longevity and quality of survival of patients with solitary mets undergoing surgical excision plus WBXRT vs. WBXRT alone (40 weeks vs. 15 weeks median survival).[34] The surgical mortality was 4% (≈ same as 30-day mortality in the XRT-only group). More patients treated with WBXRT alone die of their brain mets than those who underwent surgery. Following total removal and post-op WBXRT, 22% of patients will have recurrent brain tumor at 1 year.[57] This is better than surgery without XRT (with reported failure rates of 46%[57] and 85%[58]).

Stereotactic radiosurgery (SRS)

There has not been a randomized study to compare surgery to SRS. *Retrospective* studies suggest that SRS may be comparable to surgery.[60,68] However, a prospective (non-randomized, retrospectively matched) study[61] found a median survival of 7.5 mos with SRS vs. 16.4 mos with surgery, and a higher mortality from cerebral disease in the SRS group (with the mortality due to the SRS treated lesions and not new lesions). A local control rate of ≈ 88% has been reported, with one study also recommending WBXRT following the SRS for better regional control.[69]

Actuarial control rates at 1 year following SRS + WBXRT were 75–80% and appear to be similar to surgery + WBXRT.[46] However, SRS was unreliable in reducing tumor size.

Multiple mets

Patients with multiple mets that were totally removed have a survival that is similar to those having single mets surgically removed[26] (see above).

Recurrent metastases

Surgery is recommended for intracranial recurrence after initial surgery or SRS (Level 3).[47]

55.1.10 Carcinomatous meningitis

General information

Carcinomatous meningitis (CM) AKA (lepto)meningeal carcinomatosis (LMC). Found in up to 8% of patients autopsied with systemic cancer. CM may be the presenting finding in up to 48% of patients with cancer (before the diagnosis cancer is known). Most common primaries: breast, lung, then melanoma.[70 (p 610–2)] Always include *lymphomatous meningitis* in the differential diagnosis; see CNS lymphoma (p. 840).

Clinical

Simultaneous onset of findings in multiple levels of neuraxis. Multiple cranial nerve findings are frequent (in up to 94%, most common: VII, III, V, and VI), usually progressive. Most frequent symptoms: H/A, mental status changes, lethargy, seizure, ataxia. Non-obstructive hydrocephalus is also common. Painful radiculopathies can occur with “drop mets.”

Diagnosis

Lumbar puncture

Perform only after mass lesion has been ruled out with cranial CT or MRI. Although the initial LP may be normal, CSF is eventually abnormal in > 95%.

CSF should be sent for:

1. cytology to look for malignant cells (requires ≈ 10 ml for adequate evaluation for CM). Repeat if negative (45% positive on first study, 81% eventually positive after up to 6 LPs). May need to pass CSF through a millipore filter
2. bacterial and fungal cultures (including unusual organisms, e.g., cryptococcus)
3. tumor markers: carcinoembryonic antigen, alpha-fetoprotein
4. protein/glucose: elevated protein is the most common abnormality. Glucose may be as low as ≈ 40 mg% in about a third of patients

MRI

Contrast enhanced MRI is more sensitive in showing meningeal enhancement.[71]

CT

May show (mild) ventricular dilatation, enhancement of basal cisterns. Sulcal enhancement may also occur with involvement of the convexities.

Myelography

Spinal seeding (“drop mets”) will produce filling defects on myelography.

Survival

Untreated: < 2 months. With radiation therapy + chemotherapy: median survival is 5.8 mos (range 1–29). Chemotherapy may be given intrathecally. About half of patients die of CNS involvement, and half die of systemic disease.

55.2 Spinal epidural metastases

55.2.1 General information

Key concepts

- suspected in a cancer patient with back pain that persists in recumbency
- occurs in ≈ 10% of all cancer patients
- 80% of primary sites: lung, breast, GI, prostate, melanoma, and lymphoma
- many treatments reduce pain. Surgery + XRT in selected cases increases chances of preserving ambulation & produces a modest improvement in survival
- if no neurologic compromise or bony instability, usual treatment: biopsy (CT- or fluoro-guided) followed by XRT (surgical indications ▶ Table 55.11)
- surgery not helpful for: total paralysis > 8 hrs, loss of ambulation > 24 hrs, and not recommended for prognosis < 3–4 months survival, poor medical condition (poor PFTs…), or radiosensitive tumor

Spinal epidural metastases (SEM) occur in up to 10% of cancer patients at some time,[72] and are the most common spinal tumor. 5–10% of malignancies present initially with cord compression.[73] For other etiologies of spinal cord compression, see items marked with a dagger (†) under Myelopathy (p. 1696).

Routes of metastasis to spine:

1. arterial
2. venous: via spinal epidural veins (Batson's plexus[74])
3. perinervous (direct spread)

The usual route of spread is hematogenous dissemination to the vertebral body with erosion back through pedicles and subsequent extension into the epidural space (i.e., *anterior* epicenter). Less commonly may initially metastasize to lateral or posterior aspect of canal. Most metastases (mets) are epidural, only 2–4% are intradural, and only 1–2% are intramedullary. Distribution between cervical, thoracic, and lumbar spine is proportional to the length of the segment, thus the thoracic spine is the most common site (50–60%).

55.2.2 Primary tumors that metastasize to the spine

▶ Table 55.8 shows primary tumor types that give rise to SEM. The majority are common primaries that tend to metastasize to bone (lung, breast, prostate, renal-cell, and thyroid). Rare tumors that

Table 55.8 Sources of spinal epidural metastases causing cord compression

Site of primary	Series A	Series B[a]	Series C[b]
lung	17%	14%	31%
breast	16%	21%	24%
prostate	11%	19%	8%
kidney (renal-cell)	9%		1%
unknown site	9%	5%	2%
sarcoma	8%		2%
lymphoma	6%	12%	6%
GI tract	6%		9%
thyroid	6%		
melanoma	2%		4%
others (including multiple myeloma)	13%	29%[c]	13%

[a] series B: retrospective study of 58 patients undergoing MRI evaluation for SEM[72]
[b] series C: 75 patients with SEM out of 140 patients evaluated prospectively for back pain[76]
[c] in series B, "other" includes GI, GU, skin, ENT, CNS

may go to bone include the myxoid subtype of liposarcoma[75] (17% of these patients develop bone mets, 5-year median survival is 16%).

55.2.3 Presentation

Pain: the most common initial symptom. Occurs in up to 95% of patients with SEM.[77,78] Types of pain:

1. local pain: typically aching, experienced at the level of involvement. Increased pain with *recumbency* (especially at night) is characteristic
2. radicular: tends to be sharp or shooting, referred into dermatome of the involved nerve root. Commonly bilateral in thoracic region
3. mechanical: usually exacerbated by movement

Neck-flexion, straight-leg-raising, coughing, sneezing, or straining may also aggravate the pain.

Motor or autonomic dysfunction: the second most common presentation. Up to 85% of patients have weakness at the time of diagnosis. Leg stiffness may be an early symptom. Bladder dysfunction (urinary urgency, hesitancy, or retention) is the most common autonomic manifestation; others include constipation or impotence.

Sensory dysfunction: anesthesia, hypesthesia, or paresthesias usually occur with motor dysfunction. Cervical or thoracic cord involvement may produce a sensory level.

Other presentations: pathologic fracture. Bone metastases can sometimes produce hypercalcemia (a medical emergency).

The greater the neurologic deficit when treatment is initiated, the worse the chances for recovery of lost function. 76% of patients have weakness by the time of diagnosis.[72] 15% are paraplegic on initial presentation, and < 5% of these can ambulate after treatment. Median time from onset of symptoms to diagnosis is 2 months.[79]

Metastases to the upper cervical spine

For differential diagnosis, see Foramen magnum lesions (p. 1649), and Axis (C2) vertebra lesions (p. 1678).

Metastases to the C1–2 region comprise only ≈ 0.5% of spinal mets.[80] They typically present initially with suboccipital and posterior cervical pain, and as the lesion progresses patients develop a characteristic pain that makes it difficult to sit up (some will hold their heads in their hands to stabilize it). Possibly as a result of the capacious spinal canal at this level, only ≈ 11–15% of patients present with neurologic symptoms. 15% develop spinal cord compression,[81] and quadriplegia from atlantoaxial subluxation occurred in ≈ 6%.[81]

Anterior approaches for stabilization at this location are difficult. Pathologic fractures due to osteoblastic types of tumors (e.g., prostate, some breast) may heal with radiation treatment and immobilization. For others, good pain relief and stabilization may be achieved with radiation followed by posterior fusion.[81]

55.2.4 Evaluation and management of epidural spinal metastases

General information

There is no difference in outcome between lesions above or below the conus; thus spinal cord, conus medullaris, or cauda equina mets are considered together here as epidural spinal cord compression (ESCC). Features that help distinguish conus lesions from cauda equina are shown in ▶ Table 55.9.

Grading function

There is prognostic significance in the presenting neurologic condition. Grading scales such as that of Brice and McKissock (▶ Table 55.10) have been proposed, but are not widely used. The ASIA grading scale is more commonly applied.

Diagnostic tests

MRI in evaluating SEM

MRI without and with contrast is the diagnostic test of choice in most situations.

Table 55.9 Features distinguishing conus lesions from cauda equina lesions with metastases[82]

	Conus medullaris lesions	Cauda equina lesions
spontaneous pain	rare; when present, is usually bilateral & symmetric in perineum or thighs	may be most prominent symptom; severe; radicular type; in perineum, thighs & legs, back or bladder
sensory deficit	saddle; bilateral; usually symmetric; sensory dissociation	saddle; no sensory dissociation; may be unilateral & asymmetric
motor loss	*symmetric*; not marked; fasciculations may be present	*asymmetric*; more marked; atrophy may occur; fasciculations rare
autonomic symptoms (including bladder dysfunction, impotency...)	prominent early	late
reflexes	only ankle jerk absent (preserved knee jerk)	ankle jerk & knee jerk may be absent
onset	sudden and bilateral	gradual and unilateral

Table 55.10 Grading spinal cord function with spinal metastases (Brice & McKissock)[83]

Group	Grade	Description
1	mild	patient able to walk
2	moderate	able to move legs, but not antigravity
3	severe	slight residual motor and sensory function
4	complete	no motor, sensory, or sphincter function below level of lesion

MRI findings in spinal epidural metastases:

1. vertebral mets are slightly hypointense compared to normal bone marrow on T1WI, and are slightly hyperintense on T2WI
2. axial cuts typically show lesion involving the posterior vertebral body with invasion into one or both pedicles
3. when myelopathy or radiculopathy are present, there is usually tumor extension into the spinal canal (may not occur in lesions presenting only with local pain)
4. DWI images may help differentiate osteoporotic compression fracture from pathologic fracture[84]

Plain X-rays

Most spinal mets are osteolytic, but at least 50% of the bone must be eroded before plain X-rays will be abnormal.[85] Not very specific. Possible findings: pedicle erosion (defect in “owl’s eyes” AKA “winking owl sign” on LS or thoracic spine AP view) or widening, pathological compression fracture, vertebral body (VB) scalloping, VB *sclerosis*, osteoblastic changes (may occur with prostate Ca, Hodgkin’s disease, occasionally with breast Ca, and rarely with multiple myeloma).

Plain CT in evaluating SEM

Very good for bone detail. Often helpful for surgical planning. By itself, has low sensitivity for spinal cord compression by tumor. Sensitivity is increased with intrathecal contrast (CT-myelogram).

CT-myelogram (CT-myelo)

Indicated when MRI cannot be done (contraindications, unavailability...).

Advantages over MRI:

- Can obtain CSF (when performing LP to inject contrast) for cytological study
- Excellent bony detail
- Can be performed in patients with pacemaker/AICD, claustrophobia...

Disadvantages of myelography over MRI[72]:

- Invasive
- May require second procedure (C1–2 puncture) if there is a complete block (providers proficient in this technique are becoming fewer)

- Risk of neurologic deterioration from LP in patient with complete block
- Cannot detect lesions that do not cause bony destruction or distortion of the spinal subarachnoid space
- Up to 20% of patients with SEM have at least two sites of cord compression, MRI can evaluate region between two complete blocks, myelography cannot
- Cannot demonstrate paraspinal lesions
- Does not image spinal cord parenchyma

Positron emission tomography (PET) scan

PET scan using [18F]-fluorodeoxyglucose may be used for whole-body work-up for bone mets in patients with known cancer.[86] Sensitivity is high, but spatial resolution and specificity are low, so often must be used with CT and/or MRI.

Metastatic work-up for patients with suspected spine metastases

- CT of chest, abdomen and pelvis: assess tumor burden, staging, prognostication (which factors into decisions regarding surgery). Has superseded CXR to rule out lung lesion (primary or other mets)
- bone scan: looks for other sites of skeletal involvement
- serum prostate specific antigen (PSA) in males
- mammogram in females
- for multiple myeloma (p. 930)
- careful physical exam of lymph nodes

Management algorithm

General information

Management is dependent on the degree and rapidity of neurologic involvement.[82] Patients may be categorized into one of the three groups that follows, which determines the subsequent steps. In a patient with suspected spine mets, the goals of management are:

- assessment of neurologic involvement and timeline of neurologic changes
- delineation of the degree of spinal involvement
- determination of a histologic diagnosis: this affects management
- preservation or restoration of neurologic function
- preservation or restoration spinal stability
- controlling pain

The tools that are employed in the assessment and stabilization phase are listed under diagnostic tests above. The section that follows discusses the rapidity with which they are implemented.

A metastatic work-up (p. 924) is undertaken as time permits (a preliminary work-up, e.g., CXR and physical exam, may be all that can be initially obtained for patients in Group I, whereas more complete work-up can be done in others).

Group I—rapid progression or severe deficit

Group I characteristics

Signs/symptoms of new or progressive (hours to days) cord compression (e.g., urinary urgency, ascending numbness). These patients have a high risk of rapid deterioration and require immediate evaluation.

Management

1. dexamethasone (DMZ) (Decadron®): reduces pain in 85%, may produce transient neurologic improvement. Optimal dose is not known. No difference was found comparing 100 mg IV bolus to 10 mg.[87] Suggestion: 10 mg IV or PO q 6 hrs × 72 hrs, followed by lower dose of 4–6 mg q 6 hrs. Steroids may temporarily mask lymphoma (on imaging and at surgery); however, in this group the benefit of giving steroids usually outweighs this pitfall
2. radiographic evaluation
    a) STAT *MRI* (above)
    b) *plain X-rays* of entire spine: 67–85% will be abnormal (see above)

   c) if time permits, plain CT scan through involved levels and at least 2 levels above and below to evaluate bone for surgical planning
   d) **emergency** myelogram: indicated if MRI cannot be done (include possible C1–2 puncture on the consent). Start with a so-called "blockogram" to R/O complete block: instill small volume of contrast, e.g., iohexol (Omnipaque™) (p. 230) via LP and run the dye all the way up the spinal column; CSF is usually xanthochromic with complete block, see Froin's syndrome (p. 987)
      - if there is not a complete block: withdraw 10 cc of CSF and send for *cytology*, protein & glucose. One may then inject more contrast to complete the study
      - if complete block: do *not* remove CSF (pressure shifts via LP caused neurologic deterioration in ≈ 14% of patients with complete block,[88] whereas there was no deterioration after C1–2 puncture). In some cases, contrast can be "squeezed" past a "complete" block by injecting 5–10 ml of room air through a millipore filter.[89] Alternatively, perform a lateral C1–2 puncture (p. 1819) and instill water soluble contrast to delineate the superior extent of the lesion
      - with myelography, epidural lesions classically produce hourglass deformity with smooth edges if block is incomplete, or paintbrush effect (feathered edges) if block is complete, unlike the sharp margins (capping or meniscus sign) of intradural extramedullary lesion, or fusiform cord widening of intramedullary tumors
      - *bone scan* if time permits. Abnormal in ≈ 66% of patients with spine mets
3. treatment based on results of radiographic evaluation
   a) if no epidural mass: treat primary tumor (e.g., systemic **chemotherapy**). Local radiation therapy (XRT) to bony lesion if present. Analgesics for pain
   b) if epidural lesion, either surgery *or* start XRT (usually 30–40 Gy in 10 treatments over 7–10 d with ports extending 2 levels above and below lesion). XRT is usually as effective as laminectomy with fewer complications; for further discussion see Treatment for SEM (p. 926). Thus, *surgery* instead of XRT is considered only for the indications shown in ▶ Table 55.11
   c) **urgency** of treatment (surgery or XRT) is based on degree of block and rapidity of deterioration:
      - if > 80% block or rapid progression of deficit: emergency treatment ASAP (if treating with XRT instead of surgery, continue DMZ next day at 24 mg IV q 6 hrs x 2 days, then taper during XRT over 2 wks)
      - if < 80% block: treatment on "routine" basis (for XRT, continue DMZ 4 mg IV q 6 hrs, taper during treatment as tolerated)

Table 55.11 Indications for surgery for spinal metastases

Indications
1. unknown primary and no tissue diagnosis (CT guided needle biopsy is an option for accessible lesions). NB: lesions such as spinal epidural abscess can be mistaken for metastases[93] 2. spinal instability (see the Spine Instability Neoplastic Score (SINS) ▶ Table 55.12) 3. deficit due to spinal deformity or compression by bone rather than by tumor (e.g., due to compression fracture with collapse and retropulsed bone) 4. radio-resistant tumors (e.g., renal-cell carcinoma, melanoma...) or progression during XRT (usual trial: at least 48 hrs, unless significant or rapid deterioration) 5. recurrence after maximal XRT 6. rapid neurologic deterioration
Relative contraindications
1. very radiosensitive tumors (multiple myeloma, lymphoma...) not previously radiated 2. total paralysis (Brice and McKissock group 4) > 8 hours duration, or inability to walk (B&M group > 1) for > 24 hrs duration (after this, there is essentially no chance of recovery and surgery is not indicated) 3. expected survival: ≤ 3–4 months 4. multiple lesions at multiple levels 5. patient unable to tolerate surgery: for patients with lung lesions, check PFTs

Group II—mild and stable signs and symptoms

Group II characteristics

Mild and stable signs/symptoms of cord compression (e.g., isolated Babinski), or either plexopathy or radiculopathy without evidence of cord compression. Admit and evaluate within 24 hrs.

Management

1. for suspected ESCC, manage as in Group I except on less emergent basis. Use low dose dexamethasone (DMZ) unless radiographic evaluation shows > 80% block or if suspicion of lymphoma is high and tissue will be obtained relatively soon
2. for radiculopathy alone (radicular pain, weakness, or reflex changes in one myotome or sensory changes in one dermatome): if plain X-rays show bony lesion then 70–88% will have ESCC on myelography. If the plain film is normal, only 9–25% will have ESCC. Obtain MRI or myelogram and manage as for suspected ESCC
3. for plexopathy (brachial or lumbosacral): pain is the most common early symptom, distribution not limited to single dermatome, commonly referred to elbow or ankle. May mask coexistent radiculopathy, distinguish by EMG (denervation of paraspinal muscles occurs in radiculopathy) or presence of proximal signs and symptoms (Horner syndrome in cervical region, ureteral obstruction in lumbar region). Management:
   a) MRI is initial diagnostic procedure (CT if MRI unavailable): C4 through T4 for brachial plexopathy, L1 through pelvis for lumbosacral plexopathy
   b) if CT shows bony lesion or paraspinal mass (with negative CT, plain films and bone scan are rarely helpful; however, if done, and plain X-ray shows malignant appearing bony lesion, or if bone scan shows vertebral abnormality, perform MRI or myelogram within 24 hrs) (give dexamethasone if ESCC suspected or MRI/myelogram delayed). Management as in Group I based on degree of block, XRT ports extended laterally to include any mass shown on CT
   c) if no bony nor paraspinal lesion on MRI/CT, primary treatment of plexus tumor; analgesics for pain

Group III—pain without neurologic involvement

Group III characteristics

Back pain without neuro signs/symptoms. Can be evaluated as outpatient over several days (modify based on ability of patient to travel, reliability, etc.).

Treatment for SEM

Treatment goals and outcome

No treatment for SEM significantly prolongs life, with the possible exception of surgery for renal cell carcinoma with a solitary spine metastasis.[90] Treatment goals are palliative: pain control, preservation of spinal stability, and maintenance of sphincter control and ability to ambulate.

The most important factor affecting prognosis, regardless of treatment modality, is ability to walk at the time of initiation of therapy. Loss of sphincter control is a poor prognosticator and is usually irreversible.

The main decision is between surgery + post-op XRT, or XRT alone. As yet, no chemotherapy has been found to be useful for SEM (may help with primary). Surgery alone appears least effective for pain control (36%, compared to 67% for surgery + XRT, and 76% for XRT alone).[91] Surgery has the attendant complications of anesthetic risk, post-op pain, wound problems in 11% (further complicated by radiation),[91] and mortality in 5–6% after laminectomy and 10% after anterior approach with stabilization.[92] Therefore, surgery appears best reserved for situations described in ▶ Table 55.11.

Medical therapy

Chemotherapy is ineffective for SEM.

Bisphosphonates reduce the risk of vertebral compression fractures (VCF) by ≈ 50%, but the effect seems to abate after ≈ 2–3 years.

Promising agents undergoing trials include: denosumab (Prolia®), a RANK ligand (RANKL) inhibitor (p. 1212) that may counteract RANKL, which is overexpressed in response to lytic bony metastases.[94] The efficacy seems better than the bisphosphonates.

Vertebroplasty/kyphoplasty

Vertebroplasty/kyphoplasty (p. 1212) reduces pain associated with pathologic fractures in up to 84% [95] with an associated increase in functional outcome.[96] Kyphoplasty appears to offer comparable pain relief to vertebroplasty with lower rates of cement leakage.[96]

Relative contraindication: spinal cord compression. Unless the diagnosis has already been verified, a biopsy should be taken through one of the pedicles prior to injecting PMMA.

Radiation therapy

Radiosensitive tumors: ▶ Table 55.6 lists radiosensitivity of metastatic tumors (to brain or spine). Other radiosensitive tumors that metastasize to the spine include: myxoid liposarcoma.[97]

Treatment[98]: Dose: range = 25–40 Gy. Typical plan: 30 Gy delivered in 3 Gy fractions over 10 days (2 working weeks) to ports extending at least 1 vertebral level above and below the extent of the lesion. Timing: for initial treatment, try to start XRT within 24 hours of diagnosis; for post-op XRT, within about 14 days following surgery.

There is a theoretical risk of radiation induced edema causing or accelerating neurologic deterioration. This has not been borne out by experimental studies with the usual small daily fractions utilized. Deterioration is more likely to be due to tumor progression.[99] The spinal cord is usually the dose limiting structure in treating SEM.

Increased doses are being made possible with the application of the added precision of stereotactic radiosurgery techniques to spinal metastases.[100]

Surgical treatment

See ▶ Table 55.11 for indications for surgery.

The Spine Instability Neoplastic Score (SINS)[101] ▶ Table 55.12 was originally devised to help medical oncologists and radiation oncologists determine when surgical consultation should be sought, and to help spine surgeons assess the stability of various types of metastatic spine involvement. The decision to recommend surgery is not solely determined by stability, and must take into account prognosis, tumor type, systemic tumor burden, medical condition of the patient…

The SINS ranges from 0 to 18, and is interpreted as shown in ▶ Table 55.13

Pre-op embolization by interventional radiologist may facilitate resection with less blood loss for highly vascular tumors such as: renal-cell, thyroid, and hepatocellular. Blood supply is through the

Table 55.12 Spine Instability Neoplastic Score (SINS)[101] (see ▶ Table 55.13 for interpretation of total score)

Category	Finding	Points	Score
Mobility of involved spinal segment	junctional (occiput-C2, C7-T2, T11-L1, L5-S1)	3	**(0 - 3)**
	mobile spine (C3-6, L2-4)	2	
	semi-rigid spine (T3-10)	1	
	rigid spine (S2-5)	0	
Pain	pain relieved with recumbency and/or pain with movement/loading of the spine	3	**(0 | 1 | 3)**
	occasional, non-mechanical pain	1	
	no pain	0	
Bone lesion type	lytic	2	**(0 - 2)**
	mixed lytic/blastic	1	
	blastic	0	
Radiographic spinal alignment	subluxation or translation	4	**(0 | 2 | 4)**
	de novo deformity (kyphosis and/or scoliosis)[a]	2	
	normal	0	
Vertebral body involvement (anterior and middle column)	> 50% collapse	3	**(0 - 3)**
	< 50% collapse	2	
	no collapse with > 50% VB inolved	1	
	none of the above	0	
Posterior column involvement[b]	bilateral	3	**(0 | 1 | 3)**
	unilateral	1	
	none	0	
SINS; range: 0 (stable) to 18 (unstable) → TOTAL			**(0 - 18)**

[a] requires prior imaging or comparison of upright with recumbent imaging

[b]posterior column = facets, pedicles or CV joint (see Three column model of the spine, ▶ Fig. 72.1). Involvement = fracture or replacement by tumor

Table 55.13 Stability based on SINS ▶ Table 55.12

SINS	Stability
0-6	stable
7-12	“indeterminate” or possibly “impending instability”
13-18	unstable

intercostal arteries, and care must be taken to avoid embolizing vessels providing significant blood supply to the spinal cord, especially the artery of Adamkiewicz (p. 87).

Approaches

Laminectomy alone is *poor* for spinal metastases when the pathology is *anterior* to the cord because of poor access to the tumor and the destabilizing effect of laminectomy when metastatic involvement of the vertebral body is significant.[102,103]

Deterioration in one of the 3 major criteria (pain, continence, ambulation) occurred in 26% of patients treated with *laminectomy* alone, 20% of laminectomy + XRT, and 17% of XRT alone (roughly comparable). There is a 9% incidence of spinal instability[91] following laminectomy *without* stabilization.

In a randomized controlled trial by Patchell et al,[104] approaches directed at the location of the tumor (e.g., costotransversectomy, transthoracic approach…) with stabilization where necessary, produced better results than simple laminectomy, and surgery + XRT was superior to XRT alone (see ▶ Table 55.14). This study found a modest increase in survival, but more significant maintenance or regaining of lost ambulation. However, operative mortality with anterior decompression and stabilization was ≈ double (10%) that of laminectomy with (5%) or without (6%) stabilization in a literature review.[92]

Table 55.14 Comparing surgery + XRT to XRT alone[104]

Result	XRT	Surgery + XRT
Ambulatory after treatment	57%	84%
Days ambulatory after treatment	13	122
Ambulatory after treatment when nonambulatory before treatment	19%	62%
Mean survival (days)	100	126

Solitary spinal metastases with indolent tumors (e.g., renal cell Ca) may be candidates for attempted cure with en bloc resection (total spondylectomy).[105,106]

Laminectomy is still appropriate with isolated involvement of the posterior elements. For anterior pathology, if the posterior elements are intact, a transthoracic approach with corpectomy and stabilization (e.g., with methylmethacrylate and Steinmann pins,[107] or with cage graft and lateral plate) followed by XRT improves neurologic function in ≈ 75% and pain in ≈ 85%. A posterolateral approach (e.g., costotransversectomy) may be used for anterolateral tumor.[108] Combining a corpectomy and removal of the pedicle and posterior elements destabilizes the spine; therefore, posterior instrumentation prior to performing the corpectomy is required, followed by cage graft.[109,110,111,112,113,114,115] To access a VB via a costotransversectomy, the rib of the like numbered VB and the one below need to be removed.

55.3 Hematopoietic tumors

55.3.1 Multiple myeloma

General information

Multiple myeloma (MM) (sometimes referred to simply as myeloma) is a neoplasm of a single clone of plasma cells characterized by proliferation of plasma cells in bone marrow, infiltration of adjacent tissues with mature and immature plasma cells, and the production of an immunoglobulin, usually monoclonal IgG or IgA (referred to collectively as M-protein[116]). Circulating pre-myeloma cells lodge in appropriate microenvironments (e.g., in bone marrow) where they differentiate and expand. Although MM is often referred to in the context of “metastatic lesions” to bone, it is also sometimes considered a primary bone tumor. If only a single lesion is identified, then it is referred to as a plasmacytoma (see below).

Epidemiology

In the U.S., incidence is ≈ 1–2 per 100,000 in Caucasians, and is ≈ twice that in black people. MM accounts for 1% of malignancies, and 10% of hematologic cancers. The peak age of occurrence is 60–70 yrs of age, with < 2% of patients being < 40 yrs old. Slightly more common in males. Monoclonal gammopathy without MM occurs in ≈ 0.15% of the population, and in long-term follow-up, 16% of these develop MM with an annual rate of 0.18%.[117]

Presentation

General information

MM presents as a result of the following (italicized items are characteristic for MM):

1. proliferation of plasma cells: interferes with normal immune system function → increased *susceptibility to infection*
2. bone involvement
   a) bone marrow involvement → destruction of hematopoietic capacity → normocytic normochromic *anemia*, leukopenia, thrombocytopenia
   b) bone resorption
      - → weakening of the bone → *pathologic fractures* (see below)
      - → *hypercalcemia* (present initially in 25% of MM patients, see below)
   c) swelling or local tenderness of bone
   d) *bone pain*: characteristically induced by movement, and absent at rest
   e) spinal involvement
      - invasion of spinal canal in ≈ 10% of cases → spinal cord compression → myelopathy
      - nerve root compression (radiculopathy)
3. overproduction of certain proteins by plasma cells. May lead to:
   a) hyperviscosity syndrome
   b) cryoglobulinemia
   c) amyloidosis
   d) *renal failure*: multifactorial, but monoclonal light chains play a role

Skeletal disease

MM involvement is by definition multiple, and is usually restricted to sites of red marrow: ribs, sternum, spine, clavicles, skull, or proximal extremities. Lesions of the spine and/or skull are the usual reasons for presentation to the neurosurgeon.

Bone resorption in MM is not due simply to mechanical erosion by plasma cells. Increased osteoclastic activity has been observed.

Plasma cell tumors of the skull involving the cranial vault usually do not produce neurologic symptoms. Cranial nerve palsies can arise from skull base involvement. Orbital involvement may produce proptosis (exophthalmos).

Neurologic involvement

Neurologic manifestations can occur as a result of:

1. tumor involvement of bone causing compression (see above)
   a) tumor in spine with compression of spinal cord or nerve roots
   b) tumor in skull with compression of brain or cranial nerves
2. deposition of amyloid within the flexor retinaculum of the wrist → carpal tunnel syndrome; the median nerve itself does not contain amyloid, and therefore responds well to surgical division of the transverse carpal ligament (p. 550)
3. diffuse progressive sensorimotor polyneuropathy: occurs in 3–5% of patients with MM
   a) about half are due to amyloidosis (p. 576)
   b) polyneuropathy can also occur without amyloidosis, especially in the rare osteosclerotic variant of MM
4. multifocal leukoencephalopathy has been described in MM[118]
5. hypercalcemia: may produce a dramatic encephalopathy with confusion, delirium, or coma. Neurologic symptoms of hypercalcemia associated with MM are more common than in hypercalcemia of other etiologies
6. very rare: intraparenchymal metastases[119]

Evaluation

The diagnostic criteria for MM is shown in ▶ Table 55.15. Tests that may be used in evaluating patients with MM or suspected MM include:

1. 24 hour urine for kappa Bence-Jones protein. A monoclonal immunoglobulin light chain (MW: 22–24 kDa) present in 75–80% of patients with MM (may also occur in other conditions). Typically kappa, occasionally lambda. Monoclonal proteins cannot be detected in the urine or serum of ≈ 1% of MM patients; two or more monoclonal bands are produced in ≈ 0.5–2.5% of patients with MM.[120]
2. bloodwork:
   a) SPEP with reflex IFE and FLC
      Explanation: serum protein electrophoresis (SPEP) looks for an M-spike (identifies monoclonal immunoglobulin gammopathies), if present (reflex) immunoelectrophoresis (IEP) AKA immunofixation (IFE) looks for IgG kappa band; free light chain (FLC) assay looks for K & λ light chains. These 3 assays together are highly sensitive for MM and related plasma cell disorders
   b) CBC: anemia eventually develops in most patients with MM as myeloma cells crowd out normal bone marrow cells. It is usually of moderate severity (Hgb ≈ 7–10 gm%) with a low reticulocyte count
   c) serum creatinine: for prognostication
3. skeletal radiologic survey. Characteristic X-ray finding: multiple, round, “punched-out” (sharply demarcated) lytic lesions in the bones typically involved (see above). Osteosclerotic lesions are seen in < 3% of patients with MM. Diffuse osteoporosis may also be seen
4. technetium-99 m nuclear bone scan is usually *negative* in untreated MM (due to rarity of spontaneous new bone formation) and is less sensitive than conventional radiographs. Therefore it is not usually helpful except perhaps to implicate etiologies other than MM to explain the observed findings. After treatment, bone scan may become positive as osteoblastic activity ensues (“flare” response)
5. bone marrow biopsy: virtually all MM patients have “myeloma cells” (mutated plasma cells). Although sensitive, this is not specific and other diagnostic criteria should be sought

Table 55.15 Criteria for diagnosis of MM[a]

1. Cytologic criteria a) marrow morphology: plasma cells and/or myeloma cells ≥ 10% of 1000 or more cells b) biopsy proven plasmacytoma
2. Clinical and laboratory criteria a) myeloma protein (M-component) in serum (usually > 3 gm/dl) or urine IEP b) osteolytic lesions on X-ray (generalized osteoporosis qualifies if marrow contains > 30% plasma or myeloma cells) c) myeloma cells in ≥ 2 peripheral blood smears
[a]diagnosis requires[121]: 1A & 1B, or 1A or 1B and 2A, 2B, or 2C

Treatment

Many aspects of treatment fall into the purvey of the oncologist (see review[117]). Some aspects pertinent to neurosurgical care include:

1. XRT (p. 917): MM is very radiosensitive. Focal XRT for pain due to readily identifiable bone lesions may allow pathologic fractures to heal and is effective in spinal cord compression due to tumor
2. mobilization: immobilization due to pain and fear of pathologic compression fractures leads to further detrimental increases in serum calcium and weakness
3. pain control: mild pain often responds well to salicylates (contraindicated in thrombocytopenia). Local XRT is also effective (see below)
4. percutaneous kyphoplasty (p. 1213) may be used for some spine lesions (preferred over vertebroplasty because of reduced potential of spreading neoplasm)
5. therapy for hypercalcemia: bisphosphonates usually improve symptoms related to this
6. bisphosphonates (p. 1364) inhibit bone resorption and rapidly reduces hypercalcemia. Pamidronate is currently preferred over older agents
7. bortezomib (Velcade®): the first proteasome inhibitor, indicated for treatment of refractory MM

Prognosis

Untreated MM has a 6-month median survival. Solitary plasmacytoma has a 50% 10-year survival. If there is an solitary site of involvement but M-protein is present (i.e., essentially a plasmacytoma except for the M-protein), elimination of the M-protein following XRT indicates a 50–60% chance of remaining free of MM; if the M-protein doesn't resolve, there is a high chance of developing MM.

55.3.2 Plasmacytoma

General information

A neoplasm of a single clone of plasma cells similar to multiple myeloma (see above) but meeting the following criteria:

1. there must be no other lesions on complete skeletal survey (*not* bone scan)
2. bone marrow aspirate must show no evidence of myeloma
3. and serum and urine electrophoresis should show no M-protein

MM will develop in 55–60% of patients with a solitary plasmacytoma in 5 years, and in 70–80% by 10 yrs.

Treatment

1. local XRT provides good local control rates
2. percutaneous kyphoplasty (p. 1213): preferred over vertebroplasty because of reduced potential of spreading neoplastic cells
3. surgery for instability

56 Other Tumors, Cysts, and Tumor-Like Lesions

56.1 Other tumors

56.1.1 Olfactory neuroblastoma (ONB)

General information

Formerly called esthesioneuroblastoma, originally described in 1924, AKA olfactory esthesioneuroblastoma, AKA esthesioneurocytoma, AKA olfactory placode tumor.[1] A rare nasal neoplasm with an incidence 0.4 per 1,000,000 people.[2] Believed to arise from the olfactory neural crest cells in the upper nares, it is considered to be malignant. These tumors occur over a wide age range (3 to 90 years), with a bimodal peak between the second and third decade and a second peak in the sixth and seventh decades.

Imaging

MRI: isointense with brain on T1-weighted imaging and intermediate to high signal intensity on T2-weighted imaging and enhance heterogeneously with gadolinium. Signal characteristics may mimic meningioma. For higher stage lesions, the cribiform plate may be eroded; better seen on thin cut CT. The most important factor determining resectability is intracranial extension. Magnetic resonance aids in the distinction between extradural tumor, dural invasion, or parenchymal brain invasion. None of these are specific to this tumor.

Differential diagnosis

Includes SNUC, nasal melanoma, nasal squamous cell carcinoma, and meningioma.

Diagnosis

Endoscopic biopsy is typically performed in the otolaryngology office prior to surgery.

A clinical oncology exam should be performed, and if there is suspicion for metastatic disease a PET scan, which is sensitive for metastatic disease, should be ordered.

Clinical classification systems

The modified Kadish system[3] (which added category D to the original Kadish system[4]) is shown in ▶ Table 56.1. This classification appears to correlate with survival.[3] Alternative systems by Biller et al[5] and Dulguerov and Calcaterra[6] (see ▶ Table 56.1) attempt to subdivide the Kadish C classification; however, the more popular modified Kadish system is more frequently used.

Table 56.1 Clinical classification systems for olfactory neuroblastoma

Modified Kadish[3]	Biller et al[5]	Dulguerov and Calcattera[6]
A: Confined to Nasal Cavity	T1: Nasal/Paranasal Sinuses	T1: Nasal/Paranasal Sinuses
B: Extends to Paranasal Sinus	T2: Periorbital/Anterior Fossa Extension	T2: Erosion of Cribiform Plate
C: Local Extension (orbit or cribriform plate)	T3: Brain Involvement, Resectable Margins	T3: Periorbital/Anterior Fossa Extension
D: Distant Metastasis	T4: Unable to Obtain Negative Margins —Unresectable	T4: Brain Involvement

Pathologic grading

Hyams grading, a system used to define all upper respiratory tract carcinomas, is utilized to assess nuclear pleomorphism, mitotic activity, rosette presence, and necrosis, and summates these to produce Hyams 1–4 classification.[7] It has been shown in meta-analysis, as well as in large series, that Hyams grade 1 and 2 predict benign disease course, as compared to Hyams 3 and 4, which predict poor disease course. It is recommended that grading be performed in all cases.[8,9]

Treatment

Primary treatment is controversial. Some institutions believe in upfront combined radiation therapy and chemotherapy prior to craniofacial resection. However, most practice initial surgery, which classically consisted of endoscopic resection with negative margins for Kadish A and B lesions, and craniofacial resection (bifrontal craniotomy with associated lateral rhinotomy) for Kadish C and D lesions. However, with the advent of endoscopic techniques, the lateral rhinotomy is often replaced with a purely endoscopic approach, unless there is inferior lateral orbital or maxillary involvement, in which case the lateral rhinotomy is frequently used. Finally, some institutions are now managing Kadish stages purely endoscopically, unless they are unable to get negative margins at the time of surgery, in which case conversion to an open approach is performed or SRS is performed; however, this is controversial.

Outcome

Median overall survival is typically 7.2 ± 0.7 years.[8]

Mean progression free survival is 4.8 ± 0.7 years. The 5 and 10 year survivals are 63% and 40%.[8]

Population-based analysis of the Surveillance Epidemiology and End Results (SEER) database confirms that Kadish staging, lymph node involvement, and age at diagnosis have significant prognostic value.[10] These findings have been confirmed in a large meta-analysis recently published by Kane et al in 2010.[9] Furthermore, higher Hyams grading (grades 3 and 4) correlate with a poorer prognosis.[8,9]

Salvage treatment: For patients with recurrent disease, this typically occurs in 2 patterns: that of intracranial recurrence or those with distant metastasis.[11,12] Intracranial recurrence is typically treated with repeat transcranial resection; however, stereotactic radiosurgery is a viable option.[11,12,13] In patients with distant metastasis, those with cervical lymph node metastasis should undergo modified radical neck dissection to understand the extent of the disease. This typically leads to chemotherapy, of which platinum based therapies remain the standard of therapy at this time.[11,14,15]

56.1.2 Epidermoid and dermoid tumors

General information

AKA epidermoid or dermoid cysts.

Both are usually developmental, benign tumors that may arise when retained ectodermal implants are trapped by two fusing ectodermal surfaces. The growth rate of these tumors is linear, like skin (rather than exponential, as with neoplastic tumors).

They may occur in the following locations:

1. calvaria: skull involvement (p. 973) occurs when ectodermal rests are included in the developing cranium, epidural extension may occur with growth
2. intracranial: the most common sites include
   a) suprasellar: commonly produce bitemporal hemianopsia and optic atrophy, and only occasionally pituitary (endocrine) symptoms (including DI)
   b) Sylvian fissure: may present with seizures
   c) cerebellopontine angle (CPA): may produce trigeminal neuralgia, especially in young patient
   d) basilar-posterior fossa: may produce lower cranial nerve findings, cerebellar dysfunction, and/or corticospinal tract abnormalities
   e) within the ventricular system: occur within the 4th ventricle more commonly than any other
3. scalp
4. within the spinal canal:
   a) most arise in the thoracic or upper lumbar spine
   b) epidermoids of the lower lumbar spine may occur iatrogenically following LP; see Lumbar puncture (p. 1811)
   c) dermoids of the spinal canal are usually associated with a dermal sinus tract (p. 286) and may produce recurrent bouts of spinal meningitis.

Comparison of dermoids and epidermoids

Distinguishing features between the two tumors are shown in ▶ Table 56.2.

Table 56.2 Comparison of epidermoids and dermoid

Feature	Epidermoid	Dermoid
frequency	0.5–1.5% of brain tumors	0.3% of brain tumors
lining	stratified squamous epithelium	also include dermal appendage organs (hair follicles and sebaceous glands)
contents	keratin, cellular debris, cholesterol, occasional hair	same as epidermoids, plus hair and sebum
location	more common laterally (e.g., CP angle)	more commonly near midline
associated anomalies	tend to be isolated lesions	associated with other congenital anomalies in up to 50% of cases
meningitis	may have recurrent episodes of chemical meningitis (p. 342)	may have repeated bouts of bacterial meningitis

Epidermoid cysts

General information

Key concepts

- usually arise from ectoderm trapped within or displaced into the CNS
- predilection for: CP angle, 4th ventricle, suprasellar region, spinal cord
- sometimes AKA cholesteatoma (not to be confused with cholesterol granuloma)
- grow at linear rate (unlike exponential rate of true neoplasms)
- imaging: CSF-like mass (hi-signal on DWI MRI is the best test to differentiate)
- may produce chemical meningitis
- treatment: surgical excision. XRT has no role

AKA cholesteatoma (not cholesterol granuloma [see below]), AKA pearly tumor, AKA ectodermal inclusion cyst (see ▶ Table 56.2 for comparison to dermoids). Although epidermoids and cholesteatomas are histologically identical (both arise from epithelium entrapped in an abnormal location, epidermoids are intradural, cholesteatomas are extradural), the term cholesteatoma is most often used to describe the lesion in the middle ear where the entrapped epithelium usually arises from chronic middle ear infections which lead to a retraction pocket (rarely, may instead be congenital).

▶ **May arise from any of the following[16]:**

1. displaced dorsal midline ectodermal cell rests trapped during neural tube closure between gestational weeks 3–5
2. multipotential embryonic cell rests
3. epithelial cell rests carried to the CPA with the developing otic vesicle
4. epidermal cells displaced into CNS, e.g., by LP—see Lumbar puncture (p. 1811)—or repeated percutaneous cranial subdural taps[17]

Epidemiology

Epidermoids comprise 1% of intracranial tumors,[18] and ≈ 7% of CPA tumors. Peak age of occurrence: 40 years. No gender difference.

Histology

Epidermoids are lined by stratified squamous epithelium, and contain keratin (from desquamated epithelium), cellular debris, and cholesterol.[19] Growth occurs at a linear rate like normal skin, unlike the exponential growth of true neoplasms.[20] The cyst contents may be liquid or may have a flaky consistency. They tend to spread along normal cleavage planes and surround vital structures (cranial nerves, ICA…). Bony destruction occurs in a minority, usually with larger tumors. Rare degeneration to squamous cell cancer[21] primarily in cases of repeated recurrences after multiple surgeries.

Distinction from cholesterol granuloma

Epidermoid cysts are sometimes mistakenly equated with cholesterol granulomas,[22] possibly because of the similarity between the terms cholesteatoma and cholesterol granuloma. However, these are distinct lesions.[23] Cholesterol granulomas usually occur following chronic inflammation (usually in pneumatized portions of the temporal bone: petrous apex, mastoid air cells, middle ear space). Some differences are delineated in ▶ Table 56.3.

Table 56.3 Characteristics of epidermoid & cholesteatoma vs. cholesterol granuloma

Feature	Epidermoid	Cholesteatoma	Cholesterol granuloma
origin	ectodermal cells in abnormal location		chronic inflammatory cells surrounding cholesterol crystals (? from breakdown of RBC membranes)
	(within CNS, intradural)	(within ear, extradural)	
precursor	usually congenital, occasionally acquired, e.g., after LP (p. 1815)	usually acquired (following chronic infection ? due to epithelial cells from tympanic membrane), occasionally congenital	chronic middle ear infection or idiopathic hemotympanum
symptoms	vary depending on location	chronic hearing loss, ear drainage, pain, or numbness around ear	usually involve vestibular or cochlear dysfunction
imaging (may not reliably distinguish among these)	**CT**: low density; no enhancement; bone erosion in only 33% **MRI**: T1WI: intensity slightly > CSF; T2WI: tumor & CSF similar high intensity		**CT**: homogeneous & isodense; rim enhancement; extensive destruction of petrous bone **MRI**: increased signal on both T1WI and T2WI
gross appearance	pearly white		brown (from hemosiderin)
microscopic pathology[24]	hyperkeratotic cyst lined with stratified squamous epithelium		fibroblastic proliferation, hemosiderin-laden macrophages, cholesterol clefts, giant cell reaction
ideal treatment	aggressive near-total excision		subtotal resection followed by drainage & restoration of pneumatization[25]

Presentation

1. may present as any mass lesion in the same location
2. CPA lesions can produce V, VII, or VIII neuropathies
3. symptoms of hydrocephalus: hydrocephalus may be obstructive or communicating due to chemical meningitis
4. recurrent episodes of chemical meningitis caused by rupture of the cyst contents, which may lead to hydrocephalus
   a) symptoms include fever and meningeal irritation
   b) CSF shows pleocytosis, hypoglycorrhachia, elevated protein, and negative cultures. Cholesterol crystals may be seen and can be recognized by their amorphous birefringent appearance

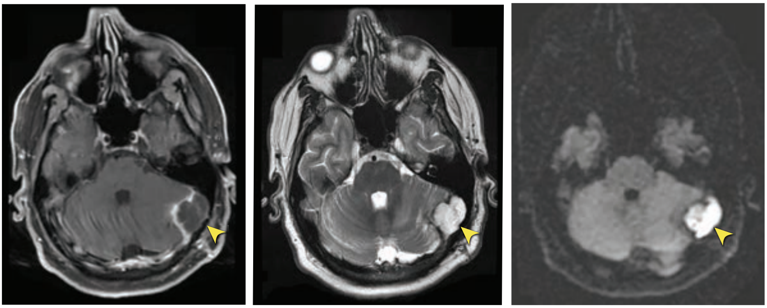
Imaging

MRI (▶ Fig. 56.1): epidermoids mimic CSF on T1WI (low signal, may be slightly > CSF) and T2WI (high signal). Other tumors are also high signal on T2WI, but most enhance with contrast on T1WI (epidermoids do not enhance). An epidermoid may pass from the posterior fossa through the incisura to the middle fossa.

Diffusion weighted imaging (DWI) is the best test to differentiate epidermoids from CSF (e.g., as in similar appearing arachnoid cyst). Epidermoids show intense signal on DWI as a result of restriction of water movement.

Treatment

Caution when removing epidermoid cysts to minimize spilling contents as they are quite irritating and may cause severe chemical meningitis (see above). Berger[16] advocates intraoperative irrigation with hydrocortisone (100 mg/L of LR) to reduce the risk of post-op communicating hydrocephalus. Perioperative IV steroids and copious saline irrigation during surgery may provide similar results. The tumor is not in the cyst wall, and the surgical plan is generally to remove as much as possible



Axial T1 with contrast Axial T2 Axial DWI

Fig. 56.1 Epidermoid (*yellow arrowheads*) of the left posterior fossa on MRI. Note: the epidermoid is bright on the DWI, whereas an arachnoid cyst would be dark (as is the CSF).

but to leave capsule adherent to critical structures such as brainstem and blood vessels as the morbidity of removal is high and a small residual does not preclude satisfactory outcome.

In spite of adequate removal, it is not unusual to see persistent brainstem distortion on post-op imaging.[23] Post-op radiation is not indicated as the tumor is benign and XRT does not prevent recurrence.[26]

Dermoid cysts

Much of the description is covered above (p. 936). Imaging findings are shown in ▶ Fig. 56.2

56.1.3 Paraganglioma (WHO grade 1)

General information

AKA chemodectoma (obsolete), AKA glomus tumor. A WHO grade 1 neuroendocrine tumor that arises from specialized neural crest cells associated with autonomic ganglia, comprised of uniform cells with neural differentiation conglomerated into compact nests (Zellballen) surrounded by a capillary network.

Paragangliomas in the *CNS* are rare, and they primarily occur in the cauda equina/filum terminale or jugulotympanic regions. Outside the CNS, paragangliomas are often designated by a name that confers the site of origin, as shown in ▶ Table 56.4.

These tumors arise from paraganglion cells (not chemoreceptor cells as previously thought; therefore the term chemodectoma is rarely used). Slow growing tumors (< 2 cm in 5 years). Histologically benign (< 10% associated with lymph node involvement or distant spread). Most contain secretory granules on EM (mostly epinephrine and norepinephrine, and these tumors may occasionally secrete these catecholamines with risk of life-threatening HTN and/or cardiac arrhythmias).

Glomus tumors may occur in 2 patterns:

1. familial: non multicentric. Up to 50%
2. nonfamilial: may be multicentric (metachronous) 5%

Pheochromocytoma

General information

Located in the adrenal gland. May be sporadic, or as part of familial syndrome (von Hippel-Lindau disease (p. 646), MEN 2A and 2B, and neurofibromatosis). Consider genetic testing if age at diagnosis is < 50 years for mutations of VHL and other genetic abnormalities (RET, SDHS, SDHB, SDHC[27]).

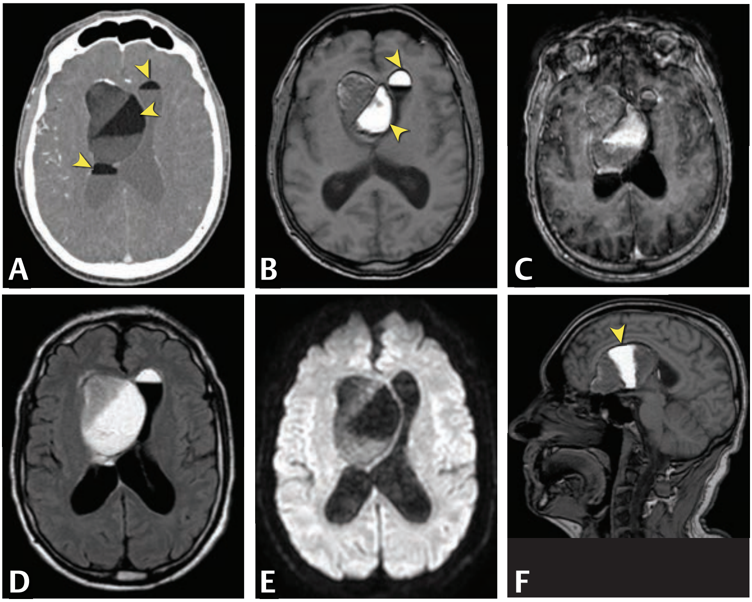


Fig. 56.2 Intraventricular dermoid cyst.
At surgery, the cyst was filled with cholesterol crystals, fat (*yellow arrowheads*), and hair.
Image: A: Axial CTA. B: Axial T1 noncontrast MRI. C: Axial T1 + contrast MRI (note the lack of significant enhancement with contrast). D: Axial FLAIR MRI. E: Axial DWI MRI. F: Sagittal T1 noncontrast MRI.

Table 56.4 Paraganglioma designation based on site of origin

Site	Designation
carotid bifurcation (most common)	carotid body tumors
auricular branch of vagus (middle ear)	glomus tympanicum
superior vagal ganglion (jugular foramen)	glomus jugulare
inferior vagal (nodose) ganglion (nasopharynx at skull base) (least common)	glomus intravagale (AKA glomus vagale)
adrenal medulla & sympathetic chain	pheochromocytoma

Laboratory studies

1. fractionated plasma metanephrines: 96% sensitivity, 85% specificity.[28] More sensitive than serum catecholamines with sporadic elevations. Pheochromocytoma is ruled out if plasma normetanephrine (NMN) < 112 pg/ml and metanephrine (MN) < 61 pg/ml. Highly suspicious if NMN > 400 pg/ml or MN > 236 pg/ml
2. 24 hr urine collection for: total catecholamines (epinephrine and norepinephrine) and metanephrines (88% sensitivity, 99.7% specificity[29]). **Note:** testing for vanillylmandelic acid (VMA) is no longer done as it does not measure fractionated metanephrines.
3. where elevation is found, a clonidine suppression test can be done. Normal response consists of a fall in plasma catecholamines to ≤ 50% of baseline and below 500 pg/ml (there will be a reduction in essential hypertension, but no change with pheochromocytoma or other tumor production)

Imaging

Indicated when laboratory tests confirm pheochromocytoma.

MRI with contrast is preferred over CT.

CT may be used when MRI is contraindicated, but is less sensitive, especially for lesions < 1 cm diameter.

123I-MIBG (iodine-123-meta-iodobenzylguanidine) scintigraphy detects extra-adrenal pheochromocytomas with 83–100% sensitivity, 95–100% specificity. If not available, 131I-MIBG may be used with 77–90% sensitivity, 95–100% specificity.

Carotid body tumors

General information

Possibly the most common paraganglioma (pheochromocytoma may possibly be more common). Approximately 5% are bilateral; the incidence of bilaterality increases to 26% in familial cases (these are probably autosomal dominant).

Clinical

Usually present as painless, slow growing mass in upper neck. Large tumors may → cranial nerve involvement (especially vagus and hypoglossal). May also cause stenosis of ICA → TIAs or stroke.

Evaluation

1. carotid angiogram: demonstrates predominant blood supply (usually external carotid, with possible contributions from vertebral and thyrocervical trunk). May also detect bilateral lesions. Characteristic finding: splaying of bifurcation
2. MRI (or CT): evaluates extent, and assesses for intracranial extension

Treatment

Resection reported to carry a high complication rate, including stroke (8–20%) and cranial nerve injury (33–44%). Mortality rate is 5–13%.

Glomus tumors

General information

Glomus tumors may be subdivided into glomus jugulare and glomus tympanicum tumors. Glomus jugulare tumors arise from the jugular bulb (in the jugular foramen at the junction of the sigmoid sinus and jugular vein). Glomus tympanicum tumors are centered higher than glomus jugulare. Glomus tumors are rare (0.6% of all head and neck tumors), yet the glomus tympanicum is the most common neoplasm of the middle ear. Glomus jugulare tumors (GJT) arise from glomus bodies, usually in the area of the jugular bulb, and track along vessels. May have finger-like extension into the jugular vein (which may embolize during resection).[30] Most are slow growing, although rapidly growing tumors do occur.

Vascular supply: very vascular. Main feeders of GJT are from the external carotid (especially inferior tympanic branch of ascending pharyngeal artery, and branches of posterior auricular, occipital, and internal maxillary), with additional feeders from petrous portion of the ICA. Glomus tympanicum tumors feed from the auricular artery.

Epidemiology

Female:male ratio is 6:1. Bilateral occurrence is almost nonexistent.

Pathology

General information

Histologically indistinguishable from carotid body tumors. May invade locally, both through temporal bone destruction and especially along pre-existing pathways (along vessels, eustachian tube, jugular vein, carotid artery). Intradural extension is rare. Malignancy, although rare, may occur. These tumors rarely metastasize.

Secretory properties

These tumors usually possess secretory granules (even the functionally inactive tumors) and may actively secrete catecholamines (similar to pheochromocytomas, occur in only 1–4% of GJT[31]). Norepinephrine will be elevated in functionally active tumors since glomus tumors lack the methyltransferase needed to convert this to epinephrine. Alternatively, serotonin and kallikrein may be released, and may produce a carcinoid-like syndrome (bronchoconstriction, abdominal pain and explosive diarrhea, violent H/A, cutaneous flushing, hypertension, hepatomegaly, and hyperglycemia).[32] During surgical manipulation, these tumors may also release histamine and bradykinin, causing hypotension and bronchoconstriction.[33]

Clinical

Symptoms

Patients commonly present with hearing loss and pulsatile tinnitus. Dizziness is the third most common symptom. Ear pain may also occur.

Signs

Hearing loss may be conductive (e.g., due to obstruction of the ear canal) or sensorineural, due to invasion of the labyrinth often with accompanying vertigo (the eighth nerve is the most common cranial nerve involved). Various combinations of palsies of cranial nerves IX, X, XI, and XII occur—see Jugular foramen syndromes (p. 102)—with occasional VII palsy (usually from involvement within the temporal bone). Ataxia and/or hydrocephalus can occur with massive lesions that cause brainstem compression. Occasionally patients may present with symptoms due to secretory products (see below).

Otoscopic exam → pulsatile reddish-blue mass behind eardrum (occasionally, lamentably biopsied by ENT physician with possible ensuing massive blood loss).

Differential diagnosis

See Cerebellopontine angle (CPA) lesions (p. 1647). The major differential is neurilemmomas (vestibular schwannomas), both enhance on CT. A cystic component and extrinsic compression of the jugular bulb are characteristic of neurilemmomas. Angiography will differentiate difficult cases.

Evaluation

Neurophysiologic testing

Audiometric and vestibular testing should be performed.

Imaging

1. CT or MRI used to delineate location and extent of tumor; CT is better for assessing bony involvement of the skull base
2. angiography: confirms diagnosis (helping to rule out vestibular schwannoma), and ascertains patency of contralateral jugular vein in event that jugular on side of tumor must be sacrificed; jugular bulb and/or vein are usually partially or completely occluded

Endocrine/laboratory studies

See also details (p. 940).

Classification

A number of classification schemes have been proposed. The modified Jackson classification is shown in ▶ Table 56.5.

Table 56.5 Modified Jackson classification of glomus tumors[34]

Type	Description	Intracranial extension
I	small; involves jugular bulb, middle ear & mastoid	none
II	extends under IAC	possible
III	extends into petrous apex	possible
IV	extends beyond petrous apex into clivus or infratemporal fossa	possible

Treatment

Surgical resection is usually simple and effective for small tumors confined to the middle ear. For larger tumors that invade and destroy bone, the relative role of surgery and/or radiation is not fully determined. With large tumors, surgery carries the risk of significant cranial nerve palsies.

Medical management

General information

For tumors that actively secrete catecholamines, medical therapy is useful for palliation or as adjunctive treatment before embolization or surgery. Alpha and beta blockers given before embolization or surgery blocks possibly lethal blood pressure lability and arrhythmias. Adequate blockade takes ≈ 2–3 weeks of alpha blocker and at least 24 hours of beta blocker therapy; in emergency, 3 days of treatment may suffice.

Alpha blockers

Reduce BP by preventing peripheral vasoconstriction.

1. phenoxybenzamine (Dibenzyline®): long acting; peak effect 1–2 hrs. Start with 10 mg PO BID and gradually increase to 40–100 mg per day divided BID
2. phentolamine (Regitine®): short acting. Usually used IV for hypertensive crisis during surgery or embolization.
   ℞: 5 mg IV/IM (peds: 1 mg) 1–2 hrs pre-op, repeat PRN before and during surgery

Beta blockers

Reduces catecholamine-induced tachycardia and arrhythmias (may also prevent hypotension that might occur if only alpha blockade is used). These drugs are not always needed, but when used 6 NB: these drugs must *not* be started before starting alpha-blockers (to prevent hypertensive crisis and myocardial ischemia).

1. propranolol (Inderal®): ℞: oral dose is 5–10 mg q 6 hrs. IV dose for use during surgery is 0.5–2 mg slow IVP
2. labetalol (Normodyne®) (p. 131): may have some efficacy in blocking α1 selective and β non-selective (potency < propranolol)

Serotonin, bradykinin, histamine release blockers

These agents may provoke bronchoconstriction that does not respond to steroids, but may respond to inhaled β-agonists or inhaled anticholinergics. Somatostatin may be used to inhibit release of serotonin, bradykinin, or histamines. Since this drug has a short half-life, it is preferable to give octreotide (p. 890) 100 mcg sub-Q q 8 hrs.

Radiation therapy

XRT may relieve symptoms and stop growth in spite of persistence of tumor mass. 40–45 Gy in fractions of 2 Gy has been recommended.[35] Lower doses of ≈ 35 Gy in 15 fractions of 2.35 Gy appear as effective and have fewer side effects.[36] Generally used as primary treatment only for large tumors or in patients too elderly or infirmed to undergo surgery. Some surgeons pretreat 4–6 mos preoperatively with XRT to decrease vascularity[37] (controversial).

Embolization

1. generally reserved for large tumors with favorable blood supply (i.e., vessels that can be selectively embolized with no danger of particles passing through to normal brain)
2. post-embolization tumor swelling may compress brainstem or cerebellum
3. may be used preoperatively to reduce vascularity. Performed 24–48 hours pre-op (not used prior to that, because of post-embolization edema)
4. caution with actively secreting tumors that may release vasoactive substances (e.g., epinephrine) upon infarction from the embolization
5. may also be used as primary treatment (± radiation) in patients who are not surgical candidates. In this case, XRT is only palliative, as tumor will develop new blood supply
6. absorbable (Gelfoam®) and non-absorbable (Ivalon®) materials have been used

Surgical treatment

General information

The tumor is primarily extradural, with extremely vascular surrounding dura.

Suboccipital approach may cause dangerous bleeding and usually results in incomplete resection. Team approach by a neurosurgeon in conjunction with a neuro-otologist (and possibly head and neck surgeon) has been advocated.[38] This approach utilizes an approach to the skull base through the neck.

ECA feeders are ligated early, followed rapidly by draining veins (to prevent systemic release of catecholamines).

Sacrifice of the jugular vein (JV) is tolerated if the contralateral JV is patent (often, the ipsilateral JV will already be occluded).

Surgical complications and outcome

The most common complications are CSF fistula, facial nerve palsy, and varying degrees of dysphagia (from dysfunction of lower cranial nerves). Dysfunction of any of the cranial nerves VII thru XII can occur, and a tracheostomy should be performed if there is any doubt of lower nerve function, and a gastrostomy feeding tube may be needed temporarily or permanently. Lower cranial nerve dysfunction also predisposes to aspiration, the risk of which is also increased by impaired gastric emptying and ileus that may occur due to reduced cholecystokinin (CCK) levels post-op. Excessive blood loss can also occur.

Even after gross total tumor removal, recurrence rate may be as high as one third.[37,39]

56.2 Cyst like lesions

56.2.1 Colloid cyst

General information

Key concepts

- slow-growing benign tumor comprising < 1% of intracranial tumors
- classically occurs in the anterior 3rd ventricle, blocking foramina of Monro bilaterally → obstructive hydrocephalus involving only the lateral ventricles (≈ pathognomonic)
- enhances minimally or not at all on CT/MRI
- natural history: risk of *sudden* death has been described, but is controversial. A small number of patients will present with acute obstructive hydrocephalus and progress to death despite appropriately rapid intervention
- treatment, when indicated, is surgical. Main options: microsurgery (transcallosal, transcortical/transventricular (only if hydrocephalus)), ventriculoscopic

AKA neuroepithelial cysts. Most commonly found in the third ventricle in the region of the foramina of Monro, but may be seen elsewhere, e.g., in septum pellucidum.[40]

Epidemiology

Estimated incidence is 3.2 per 1,000,000 per year,[41] with a prevalence of about 1 in 5800.[42] They comprise 0.5-1.5% of all intracranial tumors.[41] Usual age of diagnosis: 20–50 yrs.

There is evidence that some cases are part of familial clusters which appear to have primarily mother-to-daughter transmission.[42]

Pathogenesis

Origin: unknown. Implicated structures include: paraphysis (evagination in roof of third ventricle, rudimentary in humans), diencephalic ependyma in the recess of the postvelar arch, ventricular neuroepithelium.

Comprised of a fibrous epithelial-lined wall filled with either mucoid or dense hyloid substance. A slow growing, benign tumor.

Clinical signs and symptoms

Presenting symptoms or indications neuroimaging in patients found to have a colloid cyst in one series are shown in ▶ Table 56.6. 46% of their symptomatic patients were found to have hydrocephalus which is responsible for the most common presenting symptoms (H/A, N/V, blurred vision, ataxia, and cognitive decline).[43] A small number of patients will present with acute obstructive hydrocephalus (estimates vary from 3-35%) and despite rapid institution of CSF diversion and accompanying critical care will progress to death in 5-38%[43] (see “Sudden death” below).

Most cysts < 1 cm diameter do not produce hydrocephalus and are asymptomatic.

▶ **Sudden death.** A high rate of sudden death has been reported with colloid cysts (20% in pre-CT era[44]), but is probably overestimated. One prevailing obsolete theory was that these tumors are mobile and thus could shift position and acutely block CSF flow with resultant herniation. More

Table 56.6 Presenting symptoms or indication for neuroimaging in 163 patients with colloid cyst[43]

Feature	Symptomatic (n=65)	Incidental[a] (n=98)
headache	58 (89%)	24 (25%)
nausea/vomiting	15 (23%)	5 (5%)
vision change	14 (22%)	2 (2%)
dizziness/ataxia	13 (20%)	6 (6%)
cognitive decline	9 (14%)	11 (11%)
syncope	6 (9%)	5 (5%)
seizure	4 (6%)	2 (2%)
bradycardia	4 (6%)	0
sensory change	3 (5%)	1 (1%)
memory decline	3 (5%)	0
urinary incontinence	2 (3%)	0
trauma	1 (2%)	27 (28%)
general medical	1 (2%)	12 (12%)
weakness	1 (2%)	3 (3%)
general neurological	0	8 (8%)
stroke	0	8 (8%)
cancer staging	0	6 (6%)
intoxication	0	2 (2%)
other	0	1 (1%)

[a] Most colloid cysts in the incidental group were discovered during routine neuroimaging for unrelated conditions (trauma, stroke, nonspecific H/A, ALS...).

careful analysis reveals that nearly all patients have progressive symptoms preceding what is then seen as a precipitious deterioration. Changes in CSF dynamics resulting from procedures (LP, ventriculography…) may have also contributed in some cases.[45] Another proposed mechanism is disturbance of hypothalamic-mediated cardiovascular reflex control.[45]

Given that sudden death, while infrequent, may occur with colloid cysts, and that the literature is rife with references to this, it is imperative that the existence of this small possibility should be expounded to the patient (and this discussion should be documented) and treatment decisions should involve patient input.

Evaluation

Imaging (MRI or CT) demonstrates the tumor usually located in the anterior 3rd ventricle (▶ Fig. 56.3). Here, it often blocks both foramina of Monro causing almost pathognomonic hydrocephalus involving only the lateral ventricles (sparing the 3rd and 4th). Differential diagnosis includes basilar artery aneurysms, hamartomas, primary or secondary neoplasm, and xanthogranulomas.[46]

MRI: usually the optimal imaging technique. However, there are cases where cysts are isointense on MRI and CT is superior[47] (scrutinize the midline T1WI MRI images). When the lesion is identifiable, MRI clearly demonstrates the location of the cyst and relation to nearby structures, usually obviating an angiogram. MRI appearance: variable. Usually hyperintense on T1WI, hypointense on T2WI. Some data suggests that symptomatic patients are more likely to display T2 hyperintense cysts on MRI, indicating higher water content which may reflect a propensity for continued cyst expansion.[48] Enhancement: minimal, sometimes involving only capsule.

CT scan: findings are variable. Most are hyperdense (however, iso- and hypodense colloid cysts occur), and about half enhance slightly. Density may correlate with viscosity of contents; hyperdense cysts were harder to drain percutaneously.[49] CT is usually not quite as good as MRI, especially with isodense cysts. These tumors calcify only rarely.

✖ LP: *contraindicated* prior to placement of shunt due to risk of herniation.

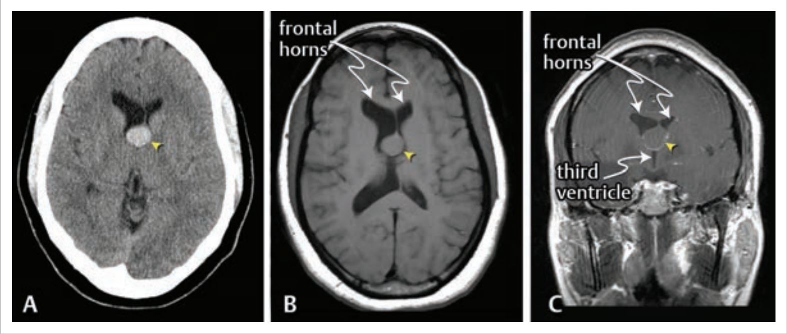

Fig. 56.3 Colloid cyst (*yellow arrowheads*) of the third ventricle.
Image: A: axial noncontrast CT scan. B: axial noncontrast T1 FLAIR MRI. C: coronal T1 contrast enhanced MRI showing relation to the normal sized 3rd ventricle and the frontal horns of the lateral ventricles (in this patient, the right lateral ventricle is enlarged, the left is not). Note: the colloid cyst does not enhance.

Treatment – general information and management options

General information

Optimal treatment remains controversial. Initially, shunting without treating the cyst was advocated.[50] The nature of the obstruction (both foramina of Monro) requires *bilateral* ventricular shunts (or, unilateral shunt with fenestration of the septum pellucidum). Presently, one form or another of direct surgical treatment of the tumor is usually recommended for some or all of the following reasons:

1. to prevent shunt dependency
2. to reduce the possibility of tumor progression
3. the mechanism of sudden neurologic deterioration may be due to factors such as cardiovascular instability from hypothalamic compression and not due to hydrocephalus

Management options

A meta-analysis of 1278 patients comparing endoscopic and various microsurgical techniques found that the microsurgical group had a significantly greater extent of resection (96.8% vs. 58.2%), lower rates of recurrence (1.48% vs. 3.91%), and lower rates of reoperation than the endoscopic group (0.38% vs. 3.0%). Both groups had similar rates of mortality (1.4% vs. 0.6%) and shunt dependency (6.2% vs. 3.9%). Overall, the complication rate was lower in the endoscopic group than in the microsurgical group (10.5% vs. 16.3%). Within the microsurgery group, the transcallosal approach had a lower overall morbidity rate (14.4%) than the transcortical approach (24.5%).[51]

Using natural history for treatment decisions

A review of 58 asymptomatic patients (average age 57 years) with incidentally discovered colloid cysts of the third ventricle with mean follow up of 79 months demonstrated the incidence of symptomatic worsening at 2-, 5-, and 10-year follow-up to be 0%, 0%, and 8%, respectively. Of the 34 patients who obtained follow up imaging, 32 demonstrated no change in cyst size or ventricular caliber. The average age of these patients was significantly higher than that of the patients undergoing surgery for symptomatic lesions (57 vs. 41) and thus may reflect a patient cohort with differing natural histories.[52]

NB: Many “asymptomatic” patients may have headaches at diagnosis. Careful evaluation of headache etiology (i.e., posttraumatic, migrainous, tension, etc.) should be undertaken to determine whether the headaches are due to the colloid cyst or if the cyst is asymptomatic.

Pollock et al[48] reviewed 155 patients with newly diagnosed colloid cysts, performing a recursive partitioning analysis, and divided patients into three classes as shown in ▶ Table 56.7.

Additionally, a significantly greater number of Class III patients had hyperintense cyst contents on T2 weighted imaging (44% vs. 13%), and symptomatic patients were more likely to have increased T2 signal (44% vs. 8%) compared to their asymptomatic counterparts. The authors suggest that asymptomatic patients with low T2 signal-containing cysts may reflect a group with low potential for cyst expansion and development of cyst-related symptoms (even in the presence of ventriculomegaly); thus they may represent a population that may be safely managed in a nonoperative fashion.[48] Nevertheless, most surgeons would recommend surgery for a patient with ventriculomegaly and symptoms such as headache even if they may not be definitely related.

Table 56.7 Classes of colloid cyst based on recursive partitioning analysis

Class	Characteristic			Symptomatic patients (% of total)	Treatment options
	Age (years)	Cyst diameter	Ventricles		
I	any	≤ 10 mm	normal	12%	May be monitored clinically and with serial imaging (CT or MRI)
II	> 50	≤ 10 mm	ventriculomegaly	50%	If asymptomatic, may be monitored clinically and with serial imaging (CT or MRI)
III	any	> 10 mm	normal	85%	Surgical removal is recommended
	≤ 50	any	ventriculomegaly		
	> 50	> 10 mm	ventriculomegaly		

Surgical treatment

Surgical options

Also see Approaches to the third ventricle.

1. transcallosal approaches: not dependent on dilated ventricles. Higher incidence of venous infarction or forniceal injury (see below)
2. transcortical approach: higher incidence of post-op seizures (≈ 5%). Not feasible with normal sized ventricles (e.g., in patient with VP shunt)
3. stereotactic drainage: see below
4. ventriculoscopic removal: see below

Transcallosal approach

Access to the 3rd ventricle via either the foramen of Monro or by interfornicial approach. Since colloid cysts tend to occur exactly at the foramen of Monro, it is *rarely* necessary to enlarge the foramen to locate the tumor. See Transcallosal approach to lateral or third ventricle (p. 1758).

Endoscopic (ventriculoscopic) resection

Ventriculoscopic resection has been shown to have a a reduced incidence of operative morbidity and overall surgical treatment cost (including reduced length of stay) when compared to microsurgery.[53] It is argued that this should be the initial procedure of choice, with craniotomy reserved for treatment failures).[54] However, endoscopic resection is associated with a significantly increased incidence of residual coagulated cyst-wall remnants compared to microsurgery. It remains to be seen whether this will ulitimatley result in an increased rate of reoperation, and how that will impact the overall patient outcome and costs.

Stereotactic drainage of colloid cysts

May be useful,[55] especially in patients with normal ventricles from shunting, but the contents may be too viscous,[56] and the tough capsule may make blind penetration difficult. Total or even subtotal aspiration may not require further treatment in some patients; however, recurrence rate is higher than with surgical removal.[57]

Early morbidity was relatively high from this procedure (not widely reported in literature), possibly from vascular injury or mechanical trauma; this has improved. May be more feasible with intraoperative ventriculography[58] or with a

Two features that correlate with *unsuccessful* stereotactic aspiration[59]:

1. high viscosity: correlates with hyperdensity on CT (low viscosity correlated with hypo- or isodense CT appearance; no MRI finding correlated with viscosity)
2. deflection of the cyst from tip of aspirating needle due to small size

Stereotactic technique[60]:

1. insertion point of stereotactic needle is just anterior to right coronal suture
2. start with sharp-tipped 1.8 mm probe, and advance to 3–5 mm beyond target site (to accommodate for displacement of cyst wall)
3. use a 10 ml syringe and apply 6–8 ml of negative aspiration pressure
4. if this does not yield any material, repeat with a 2.1 mm probe
5. although complete cyst evacuation is desirable, if this cannot be accomplished an acceptable goal of aspiration is re-establishment of patency of the ventricular pathways (may be verified by injecting 1–2 cc of iohexol)

56.2.2 Pineal cysts (PCs)

General information

Usually an incidental finding (i.e., not symptomatic), seen on ≈ 4% of MRIs[61] or on 25–40% of autopsies[62] (many are microscopic). The most common ones are intra-pineal glial-lined cysts with diameter < 1 cm. Etiology is obscure; PCs are nonneoplastic, and may be due to ischemic glial degeneration or due to sequestration of the pineal diverticulum. They have been regarded as benign, but the natural history is not known with certainty.[63] PCs may contain clear, slightly xanthochromic, or hemorrhagic fluid. In rare cases, they may enlarge, and like other pineal region masses, may become symptomatic by causing hydrocephalus by aqueductal compression,[64] gaze paresis[65] including Parinaud's syndrome (p. 101), or hypothalamic symptoms.

Positional H/As have been attributed to PCs; the theory is that the cyst could intermittently compress the vein of Galen and/or Sylvian aqueduct.[66] This remains unproven since asymptomatic compression of the vein of Galen and the quadrigeminal plate has been demonstrated on MRI.[67]

Imaging

May escape detection on CT because the cyst fluid density is often similar to CSF. MRI T1WI (► Fig. 56.4) shows round or ovoid abnormality in region of pineal recess, signal varies with protein content (isointense or slightly hyperintense). T2WI occasionally shows increased intensity.[63] Gadolinium occasionally enhances the cyst wall with a maximum thickness of 2 mm. Irregularities of the wall with nodular enhancement suggests the lesion is not a benign pineal cyst.

Epidermoid-dermoid cysts may also occur in the pineal region, and are larger and have different signal characteristics on MRI.

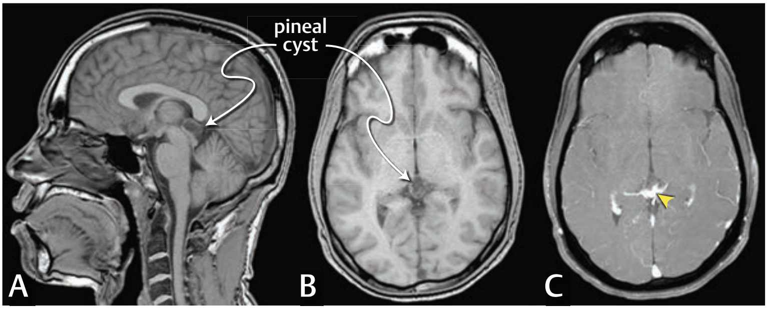

Fig. 56.4 Pineal cyst.
Dimensions: 1.5 cm AP, 1 cm height, 1.2 cm mediolateral. *Yellow arrowhead* marks contrast enchancement, probably representing the pineal gland.
Image: MRI, A: sagittal T1 noncontrast, B: axial T1 noncontrast, C: axial T1 with contrast.

Management

► **Asymptomatic PCs.** Asymptomatic PCs < 2 cm diameter with typical appearance (wall: ≤ 2 mm thick and no irregularities or nodular enhancement): are generally considered not to grow, but the natural history is not known with certainty. Risk of growing is ≈ 4% with 6 months median follow up in adults,[68] and 11% in children with 10 months median follow-up.[69] Based on this, it seems a little hard to justify not providing initial follow-up to reassure the patient and the practitioner.

A reasonable approach might consist of a 3-month follow-up MRI after the initial scan to check for rapid growth (as might occur with a neoplasm) and then if stable, annual imaging studies for an arbitrary period (some suggest 1 year[68]; 3 years is probably reasonable) to assure stability.

▶ **Symptomatic lesions or those that show changes on MRI.** Surgery to relieve symptoms and/or to obtain a diagnosis.

▶ **Hydrocephalus.** Surgical options include:

1. CSF diversion: recommended only for lesions with appearance of typical PC as it does not obtain tissue for pathology. May not relieve gaze disturbance from direct pressure on tectal plate
   a) CSF shunt
   b) endoscopic third ventriculostomy (ETV) (p. 1828). A few cases of regression of PCs after ETV have been reported[70]
2. aspiration only (stereotactic or endoscopic): may not get enough tissue for diagnosis
3. cyst excision (open or endoscopic): relieves symptoms and establishes diagnosis. Low morbidity[71]

56.2.3 Rathke's cleft cyst

General information

Rathke's cleft cysts (RCC) AKA pars intermedia cysts, are slow-growing nonneoplastic lesions that are thought to be remnants of Rathke's pouch (p. 151). They are primarily intrasellar, suprasellar extension is common, purely suprasellar presentation is rare.[72] RCC are found incidentally in 13–23% of necropsies.[73] Since the adenohypophysis arises from proliferation of the anterior wall of Rathke's pouch, RCCs and PitNET/adenomas have a similar lineage and rarely they are found together.[74] RCC are often discussed in contrast to craniopharyngiomas (**CP**) (see above). Some features are compared in ▶ Table 56.8. Recurrence after treatment is common.

Table 56.8 Comparison of craniopharyngioma to Rathke's cleft cyst

Feature	Craniopharyngioma	Rathke's cleft cyst
site of origin	anterior superior margin of pituitary	pars intermedia of pituitary
cell lining	stratified squamous epithelium	single layer cuboidal epithelium
cyst contents	cholesterol crystals	may be clear or may resemble motor oil
surgical treatment	total removal is the goal	partial excision and drainage[75]
cyst wall	thick	thin

Clinical presentation

Some symptom may be a result of mass effect; however, other symptoms may be related to inflammation that is associated with some RCCs.

- most are asymptomatic, discovered incidentally on imaging obtained for unrelated reasons
- headache occurs in 44–81% of symptomatic RCCs,[76] with sudden onset of severe H/A in up to 16%[77]
- 30–60% develop endocrine disturbance,[76] often with hypogonadism in males (producing fatigue and decreased libido), menstrual irregularities and galatorrhea in premenopausal females or panhypopituitarism in postmenopausal females. Diabetes insipidus is more common with symptomatic RCCs (up to 37%) than with pituitary adenomas (possibly due to associated inflammation)
- visual field deficit is present in 11–67%[76]

Evaluation

General workup

Workup for these lesions is the same as for sellar/suprasellar masses (p. 874) in general.

1. up to 60% have pituitary dysfunction. Endocrine workup (p. 876)is as for any sellar mass
2. visual field evaluation (p. 874)

Imaging

RCCs are typically midline, without stalk deviation.

CT: RCCs usually appear as low-density cystic lesions. One half show capsular enhancement. RCCs infrequently can erode the skull base.

MRI appearance is variable (▶ Fig. 56.5).[75] Typically high signal on T2WI. On T1WI they may be hyperintense (correlates with RCCs having proteinaceous mucinous contents) or hypointense (seen with RCCs containing clear low protein fluid). An intracystic nodule that is high signal on T1WI low signal on T2WI is described in > 75% of RCs.[78] Rule of thumb: a sellar lesion with a nodule is usually an RCC. There is no internal enhancement.

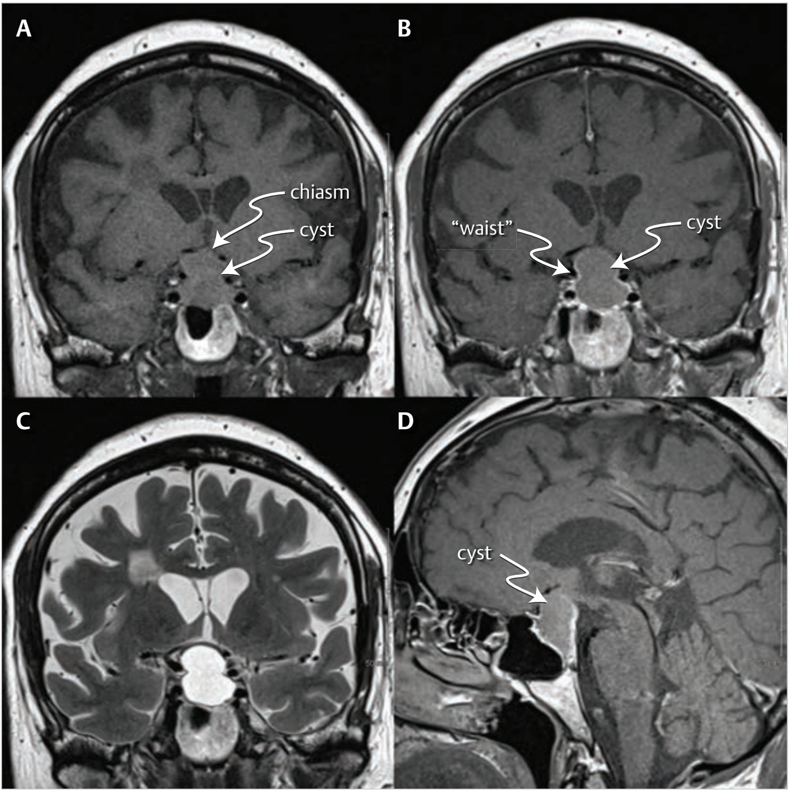

Fig. 56.5 Rathke cleft cyst.
Note: enhancment of the cyst wall but no enhancement within the cyst. The diaphragma sella creates a "waist" in the cyst where it extends into the suprasellar cistern. The optic chiasm drapes over the top of the cyst (not well visualized in this MRI).
Image: MRI. A: noncontrast T1 coronal, B: contrast enhanced T1 coronal, C: noncontrast T2 coronal, D: contrast enhanced T1 sagittal.

Natural history

Among 61 incidentally discovered RCCs, 69% showed no growth over 9 years.[79] In another series of 94 cases, only 5% increased in size and 16% actually decreased in size with 27 months mean follow-up.[80]

Management

Incidental (i.e., asymptomatic) lesions are followed with serial imaging.

Symptomatic RCCs are usually drained, most transsphenoidally, either microscopically or endoscopically, usually combined with cyst fenestration.

▶ **Reduction of recurrence rate.** Methods to reduce recurrence include techniques that promote persistence of continued drainage by maintaining patency of the fenestration. There is not sufficient evidence to recommend one method over another. Techniques include:

1. mucosal coupling: the epithelium of the RCC and the mucosa of the sphenoid sinus are connected[81]
2. stenting of the fenestration, e.g., with a bioabsorbable steroid eluting stent (e.g., PROPEL® Mini (Intersect ENT, Menlo Park, CA, USA) mometasone furoate (a synthetic antiinflammatory corticosteroid) implant, 370 mcg)
3. reduced recurrence rate has been quoted with complete cyst wall removal; however, the incidence of post-op endocrine dysfunction may be higher with this approach[76]
4. ✖ there is no strong evidence to support the use of hydrogen peroxide or alcohol irrigation in an effort to reduce the recurrence rate.

Surgical outcome

Complete cyst decompression occurs in the vast majority of cases (up to 97%[79]), with improved vision in 83–97%[79,82] in those presenting with visual disturbance. Headache improves in 71%, and endocrinopathies improve in 33–94%

Morbidity:

1. CSF leak in ≈ 10% (higher rates with extension outside the sella)
2. diabetes insipidus (DI): permanent DI occurs in up to 9% after cyst drainage, and from to 19–69% with cyst wall resection[76]
3. other risks seen with any transspehonoidal operation: internal carotid artery injury

Recurrence of cyst: reported rate is as high as 42%, but 16–18% may be more typical over 2–5 years. Higher rates of recurrence may be associated with: purely suprasellar location, inflammation and reactive metaplasia in the cyst wall, cyst infection, and use of a fat graft within the cyst cavity.

56.3 Empty sella syndrome

56.3.1 General information

Empty sella syndrome (ESS) can be "primary," "secondary," or congenital.

MRI is the imaging modality of choice (▶ Fig. 56.6). The sellar contents will follow imaging characteristics of CSF. The pituitary infundibulum may be seen traversing the sella (**infundibulum sign,**[83]

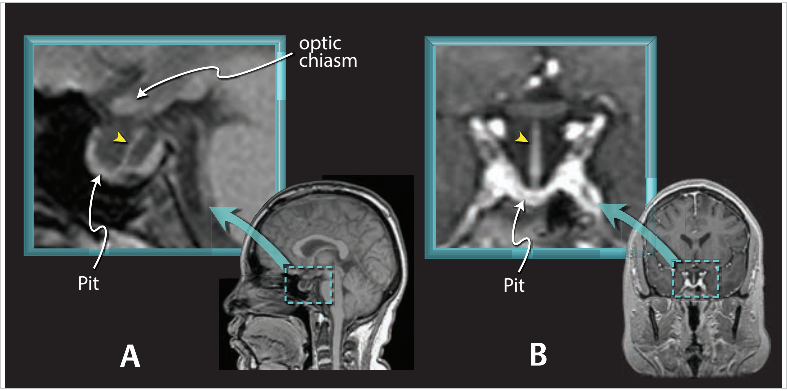

Fig. 56.6 Empty sella.
The infundibulum (AKA pituitary stalk) (*yellow arrowheads*) traverses the sella (infundibulum sign) to the pituitary gland, which is compressed against the floor of the sella.
Image: unenhanced T1 MRI, A: sagittal. B: coronal. Broken lines in inset shows from where the details are taken.
Abbreviation: Pit = pituitary gland.

which distinguishes empty sella from an intrasellar arachnoid cyst which displaces the infundibulum).

56.3.2 Primary empty sella syndrome

General information

Occurs in the absence of prior treatment of a pituitary tumor (medical, surgical, or XRT). Herniation of the arachnoid membrane into the sella turcica[84] which can act as a mass, probably as a result of repeated CSF pulsation. The pituitary gland may become compressed against the floor, and in the long term the sella itself can become enlarged (see Sella turcica (p. 227) for normal dimensions).

Frequent association: female sex (female:male ratio = 5:1), obesity, and HTN. The frequency of intrasellar arachnoid herniation is higher in patients with pituitary tumors and in those with increased intracranial pressure for any reason—including pseudotumor cerebri (p. 955)—than in the general population.

These patients usually present with symptoms that do not suggest an intrasellar abnormality including: headache (the most common symptom), dizziness, seizures… Occasionally patients may develop CSF rhinorrhea,[85] deterioration of vision (acuity or field deficit resulting from kinking of optic chiasm due to herniation into the sella), or amenorrhea-galactorrhea syndrome.

Clinically evident endocrine disturbances are rare with primary ESS; however, up to 30% have abnormal pituitary function tests, most commonly reduced growth hormone secretion following stimulation. Mild elevation of prolactin (PRL) and reduction of ADH may occur, probably from compression of the stalk. These patients show a normal PRL rise with TRH stimulation (whereas patients with prolactinomas do not).

Treatment

Surgical treatment is usually not indicated, except in the case of CSF rhinorrhea. In this setting, it is necessary to determine if there is increased ICP, and if so, if there is an identifiable cause. Simple shunting for hydrocephalus runs the risk of producing tension pneumocephalus from air drawn in through the former leak site. This may necessitate transsphenoidal repair with simultaneous external lumbar drainage, to be converted to a permanent shunt shortly thereafter. Hyperprolactinemia may be treated, e.g., with bromocriptine (p. 888) if it interferes with gonadal function.

56.3.3 Secondary empty sella syndrome

Entities associated with secondary empty sella syndrome:

1. following trauma[86]
2. after successful transsphenoidal removal or XRT for a pituitary tumor[86]
3. any cause of increased intracranial pressure, including: pseudotumor cerebri (p. 955), Chiari malformation

Often presents with visual deterioration due to herniation of the optic chiasm into the empty sella. There may be hypopituitarism from the underlying cause.

Visual deterioration may be treated with chiasmapexy (propping up the chiasm), usually by transsphenoidal approach and packing the sella with fat, muscle or cartilage. Usually done endoscopically.[87] Chiasmapexy appears to be better for improving visual field deficits than loss of visual acuity.[88]

57 Pseudotumor Cerebri Syndrome (PTCS)

57.1 General information

Key concepts

- increased ICP in the absence of a mass, hydrocephalus, CNS infection, or malignant hypertension
- primarily a neuro-ophthalmological (due to visual loss) and neurologic (due to H/A) condition
- a preventable cause of (often permanent) blindness from optic nerve atrophy
- may be primary (idiopathic intracranial hypertension) or secondary (to other conditions)
- more common in women of childbearing age who are either obese (BMI ≥ 30 kg/m^2) or who have recently gained weight than in the general population
- diagnostic criteria for pseudotumor cerebri syndrome (PTCS):
  - papilledema
  - ICP elevation ≥ 25 cm CSF on a properly performed LP
  - normal CSF analysis (no pleocytosis, elevated protein, hypoglycorrhachia, abnormal cytology, or other indication of infection or malignancy)
  - no focal neurologic deficit. Allowed exception: abducens (CN VI) palsy
  - no intracranial mass, infection, hydrocephalus, or hypertensive encephalopathy
  - normal neuroimaging. Allowed exceptions: slit-like ventricles and/or findings associated with increased intracranial pressure (empty sella (p. 951), transverse sinus stenosis, or intraorbital findings including flattening of the posterior globe (p. 587), dilated optic nerve sheath (p. 587) …)
- pseudotumor cerebri syndrome without papilledema (p. 958) (PTCSWOP) is a variant with less risk to vision and more refractory H/A. May not be the same condition
- symptoms: headache is present in > 90% of patients. However, class I evidence suggests that H/A does not correlate with opening pressure (OP) on LP
- risk of blindness correlates best with progressive visual field constriction (enlarging blind spot is characteristic) diagnosed on visual field testing, and is not reliably correlated to duration of symptoms, degree of papilledema, H/A, Snellen visual acuity, or number of recurrences
- recommended work-up:
  - ✓ brain MRI (without and with contrast) to include craniocervical junction (to R/O Chiari malformation)
  - ✓ brain MRV to evaluate dural sinuses for patients who are male or not obese, or who have progression of visual deficit despite treatment
  - ✓ LP: measure opening pressure (OP) in lateral decubitus position, and send CSF at a minimum for cell count, protein and glucose, cytology and culture (aerobic, anaerobic, fungal, and TB)
  - ✓ BP (blood pressure) to R/O hypertensive encephalopathy
  - ophthalmologic eval. Priorities: ✓ visual fields and ✓ papilledema
    Secondarily: ✓ acuity, color vision, intraocular pressure, EOM testing for abducens palsy
  - assess for common associated conditions: obstructive sleep apnea, hypervitaminosis A or use of retinoids, iron deficiency anemia…
- long-term treatment depends on weight loss and appropriate H/A treatment
- neurosurgical involvement is generally restricted to
  - acute intervention for threatened vision (in cases of fulminant PTCS (p. 967))
  - treating surgical conditions that are not PTSC (tumors, subdural hematomas, hydrocephalus, cerebral hemorrhages…)
  - in a shunted patient, diagnosing and correcting overshunting if present
  - in limited circumstances: treating refractory H/A accompanied by increased ICP, preferably under advisement of a multidisciplary panel if available
- nonsurgical treatment:
  - weight loss: the only disease modifying treatment. 6-15% weight loss usually resolves papilledema. Dietary consultation and/or bariatric surgery may help
  - medical management: provides modest improvement. Acetazolamide (Diamox®) is initial drug of choice. Alternative: Topamax
- procedural interventions: not recommended unless vision threatened. Primarily:
  - optic nerve sheath fenestration (ONSF): best for visual loss without H/A
  - CSF shunt: better than ONSF for refractory H/A associated with visual loss

- ○ stenting for bilateral focal transverse sinus stenosis: controversial. Requires antiplatelet drugs X ≈ 6 mos afterwards, which precludes other procedures (e.g., ONSF, shunting, LP…) during that time. Possible indications: a gradient > 8 mmHg (some say 5) across the stenosis in the presence of refractory increased ICP

First described in 1897 by Heinrich Quincke,[1] who called it "serous meningitis."

The nomenclature has varied widely over the years, and terms used include[2]: otitic hydrocephalus, pseudotumor cerebri (which was abandoned for a time and is now embraced), idiopathic intracranial hypertension (IIH) and the repudiated term which should be avoided "benign intracranial hypertension" (because loss of vision and reduced quality of life from debilitating headaches are not benign).

The following taxonomy has been endorsed in the U.S.[3] and abroad[4]:

► **Pseudotumor cerebri syndrome (PTCS).** A group of conditions characterized by increased intracranial pressure with no evidence of intracranial mass, hydrocephalus, infection (e.g., meningitis, especially chronic ones such as fungal meningitis), or hypertensive encephalopathy (see ► Table 57.3 for diagnostic criteria) which encompasses:

1. idiopathic intracranial hypertension (IIH) AKA primary pseudotumor cerebri. Includes: patients with obesity, recent weight gain, polycystic ovarian syndrome and thin children
2. secondary pseudotumor cerebri. Underlying causes include: conditions that increase intracranial venous pressure (dural venous sinus thrombosis, jugular vein thrombosis, superior vena cava syndrome…), certain medications and medical conditions (see below)

Either primary or secondary PTSC patients may have either:

1. papilledema (p. 586): this is considered "pseudotumor cerebri syndrome" or
2. "pseudotumor cerebri syndrome without papilledema (p. 958)" (PTCSWOP) which may be diagnosed in patients without papilledema (Frisen stage 0 ► Table 33.1) meeting PTCSWOP criteria in ► Table 57.3

57.2 Epidemiology

1. female:male ratio reported ranges from 2:1 to 8:1 (no gender difference in juvenile form)
2. obesity (BMI > 30 kg/m^2) is reported in 11–90% of cases and is not as prevalent in men with PTCS[5]
3. incidence among obese women of childbearing years[6,7]: 19–21/100,000 (compared to incidence in general population[2]: 1–2/100,000). Also occurs in patients with recent weight gain (5-15% weight gain in the past year)[8]
4. peak incidence in 3rd decade (range: 1–55 years). 37% of cases are in children, 90% of these are age 5–15 years
5. PTCS is rare in age < 3 years or > 60 years: in these age groups other causes of increased ICP should be strongly considered[3]
6. frequently self limited: recurrence rate: 9–43%
7. severe visual deficits develop in 4–12%, unrelated to duration of symptoms, degree of papilledema, headache, visual obscuration, and number of recurrences.[9] Perimetry is the best means to detect and follow visual loss

57.3 Natural history

Spontaneous resolution may occur, sometimes within months, but usually after ≈ 1 year. Papilledema persists in ≈ 15%. *Permanent* visual loss occurs in 2–24% (depending on criteria used and degree to which it is sought). Persistent H/A may occur. PTCS recurs in ≈ 10% after initial resolution.[10]

57.4 Associated conditions

57.4.1 General information

Some cases of PTCS are idiopathic (IIH), i.e., primary. The remainder are secondary to another condition, e.g., transverse sinus thrombosis, hypervitaminosis A… (see below). Many conditions cited as being associated with PTCS may be coincidental. Four criteria suggested to establish a cause-effect relationship are shown in ▶ Table 57.1.[11]

Table 57.1 Criteria for causality of PTCS by another condition[11]

1. meets Dandy's criteria (▶ Table 57.4)
2. the condition should be proven to increase ICP
3. treatment of the condition should improve the PTCS
4. properly controlled studies should show an association between the condition and PTCS

▶ Table 57.2 shows a scale[12] to rank the likelihood of association between various conditions and PTCS that is somewhat dated.

Table 57.2 Conditions that may be associated with PTCS (modified[12])

Proven association
Meets 4 criteria from ▶ Table 57.1
• obesity. Recent weight gain (5-15% weight gain in the year prior to the diagnosis of PTCS was associated with increased risk of PTCS)[8]
Likely association
Meets 3 criteria from ▶ Table 57.1
• drugs: keprone, lindane • hypervitaminosis A or use of retinoids
Probable association
Meets 2 criteria from ▶ Table 57.1
• steroid withdrawal[a] • thyroid replacement in children • ketoprofen & indomethacin in Bartter syndrome • hypoparathyroidism • Addison's disease[a] • uremia • iron deficiency anemia • drugs: tetracycline, nalidixic acid, Danazol, lithium, amiodarone, phenytoin, nitrofurantoin, ciprofloxacin, nitroglycerin
Possible association
Meets 1 criteria from ▶ Table 57.1
• menstrual irregularity • oral contraceptive use[b] • Cushing's syndrome • vitamin A deficiency • minor head trauma • Behçet syndrome
Unlikely association
Meets none of the criteria in ▶ Table 57.1
• hyperthyroidism • steroid use • immunization
Unsupported association
• pregnancy • menarche

[a] may respond to steroids
[b] may be associated with dural sinus thrombosis, see text

Other conditions not included in this list that meet minimal criteria but are unconfirmed in case-control studies[2] include:

1. other drugs: isotretinoin (Accutane®), trimethoprim-sulfamethoxazole, cimetidine, tamoxifen, fluoroquinones[13]
2. systemic lupus erythematosus (SLE)
3. obstructive sleep apnea (OSA): hypercarbia increases ICP

Conditions that may be related by virtue of increased pressure in the dural sinuses (see below):
1. otitis media with petrosal extension (so-called otitic hydrocephalus)
2. radical neck surgery with resection of the jugular vein
3. hypercoagulable states

57.4.2 Venous hypertension and sinovenous abnormalities

Venous hypertension has often been proposed as a unifying underlying cause of PTCS. Abnormalities of the dural sinuses, including thrombosis, stenosis,[14] obstruction, or elevated pressure (reaching levels as high as 40 mm Hg) have been demonstrated in a number of studies. While these findings may underlie a number of cases, in many cases they may actually be epiphenomena (e.g., venous hypertension may be due to compression of the transverse sinuses by elevated intracranial pressure[15]), and it is unlikely that such abnormalities will explain all cases.

Bilateral sinovenous stenosis was seen (using 3D gadolinium-enhanced MRI venography) in 27 of 29 patients with PTCS and in only 4 of 59 controls.[14]

57.4.3 CSF fistula (leaks)

A subgroup of PTCS patients also have CSF fistula.[16] It is possible that the fistula arises as a result of chronic increased ICP (many years) causing erosion of the skull base and dural defects.[17] CSF fistula may actually protect against papilledema in patients with PTCS,[18] and cases have been reported where repair of the fistula results in increased ICPs to levels similar to PTCS without CSF fistula.[17] Furthermore, fistula repair has a higher rate of failure if the elevated ICP is not also treated.[17]

57.5 Diagnostic criteria

Diagnostic criteria are summarized in ▶ Table 57.3. Details of the criteria components appear in following sections.

Modified[21] Dandy's criteria[22] are still referenced especially in research articles (e.g., the IIHTT[21]), and are shown in ▶ Table 57.4.

▶ **Pseudotumor cerebri syndrome without papilledema (PTCSWOP).** May be diagnosed in patients without papilledema (Frisen stage 0 ▶ Table 33.1) meeting criteria in ▶ Table 57.3. Diagnoing PTCSWOP can be difficult, and subtle findings should be ruled out by an experienced trained observer.[23] Papilledema may not be discernible in the presence of optic atrophy.

This may not be the same disease entity as PTCS[3] Compared to patients with papilledema, PTCSWOP patients typically have:
1. lower opening pressure on LP: mean: 30.9 cm CSF (which is still abnormally elevated), vs. 37.3 in those with papilledema
2. higher incidence of photopsia (flashes of light)
3. higher incidence of non-physiologic visual field constriction[23] which tend not to progress over time[23,24]
4. lower incidence of abducens palsy
5. higher incidence of normal visual fields on presentation[23]
6. H/A that are more refractory to treatment[23,25]
7. preserved venous pulsation on funduscopy[23]

57.6 Clinical findings

57.6.1 Symptoms

See references.[11,26,27,28]
1. headache (H/A), see details (p. 960)
   a) the most common symptom, reported in > 90%[29] (range: 76–99%)
   b) results in significant disability and reduced quality of life[30]
2. tinnitus: 52-61%. The causal relationship with PTCS has been demonstrated by resolution of these symptoms with reduction of CSF pressure. Usually pulse synchronous. Described as rushing noise. May be unilateral (in these, tinnitus may be reduced by ipsilateral jugular vein compression + ipsilateral head rotation)
3. visual loss, see details (p. 961)
   - transient visual obscuration (TVO): 68-72%

Table 57.3 Diagnostic criteria for pseudotumor cerebri syndrome (PTCS)[3]

Criteria	PTCS		PTCS without papilledema	
	Definite	Probable	Definite	Suggested
papilledema[a]	+	+	-	-
normal neurologic exam[b]	+	+	+	+
normal neuroimaging[c]	+	+	+	+
normal CSF composition[d]	+	+	+	+
OP > 25 cm CSF on LP[e]	+	-	+	+
abducens nerve palsy (p. 598) [f]			+	-
≥ 3 neuroimaging criteria[g]			-	+

[a] (see text (p. 960) for description) may be asymmetric or (uncommonly) unilateral. NB: papilledema may not be reliably diagnosable in the presence of optic atrophy

[b] exception: cranial nerve abnormalities (usually VI or VII). For other deficits (e.g., encephalopathy, focal deficit...) other diagnoses should be sought

[c] MRI (or CT if MRI cannot be done) without and with contrast. May show findings of increased ICP (see g below), but must show normal brain parenchyma without hydrocephalus, mass or structural lesion, and

- for typical patient (specifically: obese (BMI ≥ 30 kg/m^2) female adult or adolescent[19]):
  no abnormal meningeal enhancement
- for others (men, non-obese women, prepubescent children, and patients with progressive visual loss despite therapy):
  no abnormal meningeal enhancement and normal MRV

NB: meningeal enhancement may occasionally be seen shortly after an LP

[d] none of the following: pleocytosis, elevated protein, hypoglycorrhachia, abnormal cytology or other indication of infection or malignancy

[e] opening pressure on a properly performed LP (p. 962) (see text):
in adults, or children who are not sedated or obese: ≥ 25 cm CSF,
in children who are sedated or obese: ≥ 28 cm CSF

[f] unilateral or bilateral, may be complete or incomplete. Produces esotropia (inward eye deviation)

[g] ≥ 3 neuroimaging criteria suggestive of increased ICP:

1. empty sella ▶ Fig. 56.6 (85% of PTCS had partial or complete empty sella)[20]
2. flattening of the posterior globe (▶ Fig. 33.1)
3. optic nerve sheath distension (▶ Fig. 33.1) with or without a tortuous optic nerve
4. transverse venous sinus (TVS) stenosis (but not thrombosis) is present in most cases of PTCS[3] (see MRV (p. 964) for details)

Table 57.4 Modified modified Dandy's criteria for PTCS

- signs & symptoms of increased ICP
- no localizing signs (other than possible Cr. N VI palsy[a] in an otherwise awake and alert patient)
- increased CSF pressure without chemical or cytological CSF abnormalities
- normal neuroimaging (especially no intracranial mass) aside from small ventricles and findings of increased ICP

[a] abducens palsy may result from ↑ ICP (p. 598)

  - blurry vision:32%
  - afferent visual pathway injury: often reversible but may be permanent
4. diplopia: 18-30%. More common in adults, usually horizontal due to VI nerve palsy
5. less common or uncharacteristic symptoms
   a) neck stiffness (30–50%) or neck pain (42%)
   b) ataxia: 4–11%
   c) acral paresthesias: 25%
   d) back pain: 53%
   e) nausea: 32% (actual vomiting is less common)
   f) retrobulbar eye pain on eye movements
   g) arthralgia: 11–18%
   h) dizziness: 32-52%
   i) fatigue
   j) reduced olfactory acuity

NB: Worsening of any of the above symptoms with postural changes that increase ICP (bending over, Valsalva maneuver…) is characteristic in PTCS.

▶ **Headache in PTCS.** According to The International Classification of Headache Disorders, 3rd edition (ICHD-3),[31 (p 99)] H/A attributable to PTCS is a H/A in a patient with a nonvascular intracranial disorder known to cause H/A (here: increased ICP documented by OP ≥ 25 cm on LP) that is not better accounted for by another ICHD-3 diagnosis, and fulfills at least 2 of the following*

1. H/A developed in temporal relation to PTCS or led to its discovery
2. H/A worsens in parallel to worsening of PTCS (i.e., increasig ICP) and/or improves in parallel to improvement of PTCS (e.g., by reducing ICP)
3. H/A are typical for PTCS

* This definition has been challenged, since recent Class I evidence in a study of 165 PTCS patients with papilledema and mild vision loss[29] found:

1. there are no typical H/A characteristics for PTCS. H/A phenotype in PTCS changes over time, and is often mixed. 93% of patients with H/A in the IIHTT had features consistent with definitie or probable migraine (68%) or tension H/A (25%). Non-migraine H/A phenotypes may be exacerbated by increased ICP
2. H/A in PTCS did not correlate with opening pressure, BMI, papilledema grade or use of acetazolamide. 62% of patients continued to have H/A after successful treatment of increased CSF pressure[32]
3. ★ despite the fact that patients and providers perceive that H/As are linked to CSF pressure and that lowering CSF pressure will improve H/A control, evidence demonstrates that H/A and CSF pressure are clinically independent features of PTCS

NB: the findings in patients recruited to the study may not be generalizable e.g., to a patient who presents to the E/R with H/A and an occluded shunt.

Medication overuse headache (MOH): medication overuse (which can lead to medication overuse H/A) was found in 37% of H/A patients in the IIHTT.[29] MOH diagnostic criteria[31 (p 122)]:

1. H/A occurring ≥ 15 days/month in a patient with pre-existing primary H/A, developing as a result of regular overuse of H/A medication ≥ 10 days/month (for opioids, combined preparations, ergotamines or triptans) or ≥ 15 days/month (for NSAIDs, APAP, ASA)
2. regular overuse for > 3 months
3. not better accounted for by another ICHD-3 diagnosis

MOH usually (but not always) resolve after medication overuse stops.

57.6.2 Signs

General information

- signs are generally restricted to the visual system (see below)
- ✖ paradoxically *absent*: altered level of consciousness in spite of high ICP
- the presence of a focal neurologic deficit, or any unexplained cranial nerve deficit (except for abducens palsy) should prompt a search for an alternative diagnosis to PTCS
- the infantile form of PTCS may have only enlarging OFC, is frequently self-limited, and usually requires only follow-up without specific treatment

Eye findings in PTCS

Ophthalmologic consultation is generally recommended, especially in questionable cases.

1. papilledema
   a) the sine qua non of PTCS
   b) if papilledema is absent, PTCS without papilledema (PTCSWOP) may be diagnosed if the diagnostic criteria for that are met (▶ Table 57.3 [3,23,33])
   c) findings: optic disc elevation, blurring of the disc margin, peripillary halo, obscuration by nerve fiber layer of blood vessels crossing the disc margin, venous distension, and overlying of peripapillary hemorrhages, exudates, or cotton-wool spots[3]
   d) usually bilateral, may be asymmetric, infrequently unilateral[34]
   e) may be mild (subtle nerve fiber elevation)
   f) may be absent in cases of optic atrophy or resolved prior optic disc swelling[3]

   g) other etiologies that must be ruled out include: optic neuritis, anterior ischemic optic neuropathy, neuroretinitis, pseudopapilledema (p. 588) (includes optic nerve head drusen)
2. abducens nerve (Cr. N. VI) palsy: 20%; a false localizing sign (p. 598). The esotropia ranges from < 5 prism diopters dysconjugate angle in primary gaze to > 50[10]
3. ★ visual field defect: correlates with visual loss more closely than other findings (see below)
4. visual acuity: relatively insensitive assessment of visual function in PTCS (see below)
5. loss of color vision: not sensitive for early papilledema-related optic atrophy

57.6.3 Visual loss in PTCS

General information

Prevalence in PTCS: 48–68% (lower numbers generally come from population-based samples).

Visual loss in PTCS may occur early or late, and is not reliably correlated to duration of symptoms, papilledema, H/A, visual acuity (as tested with a standard Snellen eye chart), or number of recurrences. Visual loss is usually gradual and spares central vision until late in the course[35] and thus may not be noticed by the patient until profound. In some cases visual loss can be sudden.

Visual field deficits are the most sensitive means for detecting visual loss in PTCS.

Pathomechanics

Increased ICP is transmitted along the optic nerve sheath → circumferential compression of the retinal ganglion cell axons at the level of the lamina cribrosa.[10]

Manifestations

1. transient visual obscurations (TVO): graying or blacking out of vision. Lasts ≈ 1 second. Uni- or bilateral. Typically occur with eye movement, bending over, or Valsalva maneuver. Directly proportional to severity of papilledema. Frequency of TVOs parallels ICP elevation, but doesn't correlate with permanent visual loss
2. ★ visual field deficits: the most sensitive measure of visual impairment in PTCS, found in 96% of 50 patients in one prospective series.[36] Visual field defects are diagnosed by perimetry (p. 589) (e.g., Goldmann or Humphrey). Automated perimetry can be quantified (to generate a measurement for comparison) as the perimetric mean deviation (PMD) (p. 589)
   a) enlarged blind spots are the classic field defect in PTCS, but are rarely noticed by the patient until there is encroachment on macular vision (fixation)[35]
   b) early changes[35]: constriction of fields usually with nasal quadrant defect ("nasal step") and arcuate defects (a curved visual defect) neither of which cross the horizontal meridian
   c) late: central vision is affected. Findings include: concentric constrictions, enlarged blind spot, cecocentral scotomas…[35]
3. less common visual symptoms[37]: blurry vision (32%), diplopia (18%) (usually horizontal, may be due to abducens palsy)

57.7 Differential diagnosis

1. true mass lesions: tumor, cerebral abscess, subdural hematomas, rarely gliomatosis cerebri may be undetectable on CT and will be misdiagnosed as PTCS
2. hydrocephalus: typically ventricles are enlarged. Patients generally have obtundation, lethargy, vomiting… Some patients with reduced cerebral compliance may develop increased ICP without ventriculomegaly
3. cranial venous outflow impairment (some authors include these in IIH,[38] others do not)
   a) dural sinus thrombosis (p. 1594)
   b) congestive heart failure
   c) superior vena cava syndrome
   d) unilateral or bilateral jugular vein or sigmoid sinus[39] obstruction
   e) hyperviscosity syndromes
   f) Masson's vegetant intravascular hemangioendothelioma[40]: an uncommon, usually benign lesion that may rarely involve the neuraxis (including intracranial occurrence). Not definitely neoplastic. Organizing thrombi develop endothelialized projections into the vessel lumen. Must be distinguished from other conditions such as angiosarcoma
4. Chiari I malformation (CIM) (see Chiari-pseudotumor cerebri syndrome (p. 301))
   a) CIM may produce clinical findings similar to PTCS

   b) 6-21% of PTCS patients have tonsillar descent ≥ 5 mm below the FM on MRI[38,41,42]
   c) ≈ 5% of patients with CIM have papilledema[10]
   d) if severe, LP is contraindicated
   e) in some cases, tonsillar descent may be a result of intracranial hypotension (p. 421) (low CSF pressure) possibly as a result of a spinal CSF leak[43]
5. infection (CSF will be abnormal in most of these): encephalitis, arachnoiditis, meningitis (especially basal meningitis or granulomatous infections, e.g., syphilitic meningitis, chronic cryptococcal meningitis), chronic brucellosis, cat scratch disease (in rare cases may produce neuroretinitis[44])
6. inflammatory conditions: e.g., neurosarcoidosis (p. 198), SLE
7. vasculitis: e.g., Behçet's syndrome
8. metabolic conditions: e.g., lead poisoning
9. **malignant hypertension**: (DBP ≥ 120 mm Hg or SBP ≥ 180 mm Hg[45]). May produce H/A and bilateral optic disc edema, which can be indistinguishable from papilledema. May also produce hypertensive encephalopathy (p. 202). Check BP in all PTCS suspects
10. meningeal carcinomatosis
11. Guillain-Barré syndrome (p. 193): CSF protein is usually elevated
12. glaucoma: visual field defects of PTCS mimic those of glaucoma except that glaucoma does not typically have an enlarged blind spot[35]
13. following head trauma

57.8 Evaluation

57.8.1 Overview

Investigations that may help confirm the diagnosis, or rule out conditions that may mimic PTCS, or identify underlying causes of secondary PTCS:

1. history to identify other possible causes of increased ICP (▶ Table 57.2)
2. VS: check BP to R/O malignant HTN (which can cause optic disc edema, see above)
3. ophthalmologic evaluation. Includes: dilated funduscopic exam for papilledema (see below) and formal visual field testing (to rule-out visual loss)
4. routine serum labs: CBC (to rule-out anemia), electrolytes, PT/PTT
5. imaging:
   a) cerebral MRI without and with contrast for all patients (see details below). CT without and with contrast is performed if MRI is not an option
   b) contrast MRV (p. 964): obtain in atypical patients (pre-pubertal children, males, non-obese females) or in patients with progressive visual loss despite therapy. In practice, this is usually ordered along with the initial MRI
6. LP: measure opening pressure **(OP)** with unsedated patient in the lateral decubitus position (see below), and obtain CSF for laboratory analysis (no proven benefit of large volume tap)
7. evaluation for obstructive sleep apnea (hypercarbia increases ICP)
8. W/U for systemic conditions (e.g., sarcoidosis or SLE if other findings are suggestive, e.g., cutaneous nodules, hypercoagulable state…)

57.8.2 Ophthalmologic evaluation

A thorough exam consists of all of the following. The first 2 items are the most critical.

1. **dilated funduscopic exam** for papilledema ± fundus photographs
2. **visual field testing** may be done at bedside initially by a proficient examiner, however formal testing using quantitative perimetry with evaluation of size of blind spot and determination of perimetric mean deviation (PMD) (p. 589) should be done as soon as practical
3. visual acuity testing
4. color vision testing
5. intraocular pressure measurement

57.8.3 Lumbar puncture

Ifcontraindications to LP (p. 1811) have been ruled out on neuroimaging, perform an LP to 1) measure opening pressure and, 2) to obtain CSF for analysis. The benefit of removing a large volume of CSF (≥ 20 ml) is uncertain.[3]

Opening pressure (OP): key requirements for a properly performed LP to diagnose PTCS:

1. position: lateral decubitus position (requisite for diagnosis,[3]) measurement is most accurate in this position without knee flexion. Other positions may increase ICP:
    a) prone position: typically used for LP under fluoroscopy, may ↑ intra-thoracic pressure → decrease venous return from the brain → increased ICP
    b) sitting position: increases measured pressure due to column of CSF above the needle
    c) if the LP needle has to be inserted with the patient prone or sitting, once CSF is coming through the needle, replace the stylet and reposition the patient to the lateral decubitus and then remove the stylet to accurately measure OP
    d) knee flexion may increase ICP (controversial in children[46])
2. avoid sedation which may cause hypoventilation → hypercapnia → increased ICP)[47]
3. keep the base of the manometer level with the right cardiac atrium
4. avoid valsalva maneuver[48] (including patient crying or forced knee-chest position)
5. magnitude: the higher the OP, the more likely that it is pathologically elevated.[37] Suggested cutoffs:
    - OP < 25 cm CSF: normal
    - ★ **OP ≥ 25 cm CSF**: required for diagnosis of PTCS by criteria,[3] however there is some dissent
    - OP ≥ 30 cm CSF: almost universally accepted as abnormally elevated
    - in prepubertal children: OP ≥ 28 cm CSF (or ≥ 25 cm if the child is not sedated and not obese) meets diagnostic criteria[3]

    NB: OP on LP is a snapshot of CSF pressure. Diurnal variations in CSF pressure may occasionally cause a falsely low (i.e., normal) reading. ∴ If clinical suspicion is high, an LP at a different time of day or continuous ICP monitoring may be required
6. CSF analysis to rule out infection (especially chronic, e.g., fungus, TB, or Lyme disease), inflammation (e.g., sarcoidosis, SLE), or neoplasm (e.g., carcinomatous meningitis). Minimum:
    a) protein/glucose
    b) cell count
    c) routine and fungal cultures
    d) cytology if suspicion of carcinomatous meningitis

57.8.4 MRI of the brain

Intraparenchymal abnormalities are usually absent or minimal.

Slit ventricles are common (however, the incidence may be no higher in PTCS than in age-matched controls[49]).

Tonsillar ectopia (Chiari I) is more prevalent in PTCS than controls (see above)

Most findings are those of increased ICP (not specific just for PTCS):

a) empty sella (p. 951) in 30–70%. Includes partially empty sella or decreased pituitary height
b) dural sinuses stenosis: (MRV is more sensitive—see below for findings)
c) Meckel's cave enlargement[50] ▶ Fig. 57.1 or compression[51] which may depend on the patency of the opening (porus trigeminus)

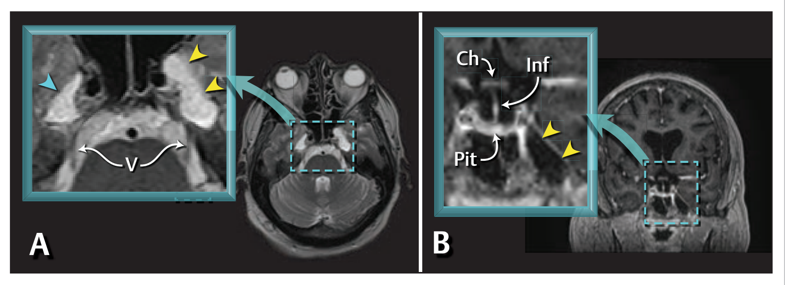

Fig. 57.1 Dilated Meckel's cave.
Image: MRI A: axial T2, B: coronal T1. Meckel's cave is mildly dilated on the right (*blue arrowhead*), and markedly dilated on the left (*yellow arrowheads*). The patient also has an empty sella demonstrating the "infundibulum sign" in B (see also ▶ Fig. 56.6).
Abbreviations: Ch = optic chiasm; Inf = infundibulum (pituitary stalk); Pit = pituitary gland; V = trigeminal nerve (Cr.N. V) as it crosses the CPA cistern.

d) intraorbital findings consistent with increased ICP include[10]:
  a) flattening of the posterior globe/sclera: (▶ Fig. 33.1) occurs in 80%
  b) enhancement of the prelaminar optic nerve (the prelaminar layer is essentially the middle layer of the retina): in 50%
  c) distention of the perioptic subarachnoid space (optic nerve sheath): (▶ Fig. 33.1) in 45%
  d) vertical tortuosity of the orbital optic nerve: in 40% (the intraorbital optic nerve normally has a slight "S" shape)
  e) intraocular protrusion of the prelaminar optic nerve head: in 30%

57.8.5 MRV (magnetic resonance venography)

MR venography (MRV) has largely replaced conventional venography to rule out dural sinus or venous thrombosis or AV fistula.

Indications: atypical PTCS patients (i.e., patients who are not both obese and female) or those with progressive visual loss despite therapy. If the first MRV is negative or equivocal and the suspicion of sinus thrombosis is high, a CT venogram, catheter angiogram or second MRV is indicated.

Sequences: maximum intensity projection (MIP) reconstructions from gadolinium-enhanced MRV is recommended, since time-of-flight MRV tends to overestimate stenosis.[52]

Findings: attenuation/stenosis (but not thrombosis) of dural venous sinuses is present in most cases of PTCS.[3] Includes bilateral transverse venous sinus (TVS) stenosis or stenosis of a dominant TVS (normal transverse sinuses are often asymmetric, with the right usually larger/dominant) (▶ Fig. 57.2). Bilateral TVS stenosis is uncommon in healthy individuals[53]

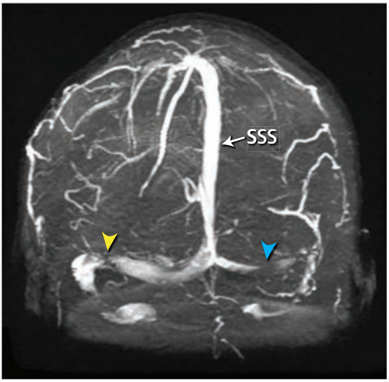

Fig. 57.2 Transverse sinus stenosis.
Image: coronal gadolinium MRV showing focal high-grade stenosis within the distal third of the dominant (larger) right transverse sinus (*yellow arrowhead*) and a longer area of stenosis in the non-dominant left transverse sinus (*blue arrowhead*). Abbreviation: SSS = superior sagittal sinus.

CT of the brain

MRI and MRV are preferred. Brain CT scan is less sensitive, but may be used if MRI is not an option. CT without and with IV contrast is usually adequate to R/O intracranial mass as a possible cause of intracranial hypertension. CT venography (CVT) may evaluate dural sinus compression.

57.9 Treatment and management

57.9.1 Treatment goals

- protect vision
- minimize headache morbidity

57.9.2 Interventional options

Overview

Initial management: usually consists of attempt at weight loss and pharmacologic therapy. However some patients will have acute (fulminant (p. 967)) or progressive or persistent symptoms and require more aggressive intervention. Treatment options are shown below, management guidelines follow (p. 967).

▶ **Treatment options.** This is only a catalogue of options. For *guidelines* on how to use them, see the list (p. 967) that follows.[37]

1. weight loss
2. medical treatment
   a) fluid and salt restriction, usually combined with carbonic anhydrase inhibitors
   b) carbonic anhydrase inhibitors and other diuretics: slow CSF production (see below)
   c) headaches should be characterized by phenotype and treated accordingly (p. 960) by a practitioner experienced in H/A management
   d) ✖ corticosteroids are not recommended due to the lack of sound clinical evidence.[37] Prolonged use may also exacerbate weight gain and increase the risk of venous thrombosis
3. treat obstructive sleep apnea (OSA) if present (hypercarbia increases ICP): e.g., CPAP
4. *surgical therapy*only for cases refractory to above, or where visual loss is progressive or is severe initially or unreliable patient
   a) CSF diversion (shunts): see below
   b) optic nerve sheath fenestration (p. 966) (ONSF)
   c) procedures that may be reserved for very specific situations
      - serial LPs: remove up to 30 ml to halve OP, perform qod until OP < 20 cm CSF, then decrease to q wk. Using large gauge needle (e.g., 18 Ga) may help promote a (desirable) post-LP CSF leak into subcutaneous tissues. LPs may be difficult in obese patients. Not recommended routinely.[37]
        Side effects: include sciatica from nerve root irritation, acquired cerebellar tonsillar herniation (p. 456), spinal H/A (from intracranial hypotension), back pain, risk of spinal hematoma (epidural or subdural)
      - decompressive craniectomy, usually subtemporal decompression (p. 967)
5. endovascular procedures (p. 966): transverse sinus stenting

Weight loss

This is the only disease-modifying therapy for PTCS. Patients with BMI ≥ 30 kg/m^2 should be counseled regarding weight management in a sensitive manner. The amount of weight loss required to arrest PTCS is not known. 15% weight loss was required in one cohort,[54] 6% weight loss resulted in 3 Frisen papilledema grade improvement (▶ Table 33.1) in a smaller study.[55]

NB: resolution of PTCS is too slow for acutely threatened vision. Also, symptoms often recur if the weight is regained.

- dieting: uncontrolled studies[56] suggest that this is effective, but it is difficult to accomplish and maintain
- bariatric surgery: gastric bypass, laparoscopic banding… may help

Diuretics

1. carbonic anhydrase (CA) inhibitors:
   a) *acetazolamide* (Diamox®): has been extensively studied.[21,57,58,59] Conclusion: when combined with a low-sodium weight-reduction diet, acetazolamide provides a modest improvement in papilledema, ICP and QOL,[21] but its use is often limited by side effects.[37] Has not been shown to be effective for treating H/A alone.
      ℞ start at 125–250 mg PO q 8–12 hrs, or long-acting Diamox Sequels® 500 mg PO BID. Increase by 250 mg/day until symptoms improve, side effects occur. 1 gm/d is usually tolerated,[60] 3 gm/d is a usual upper limit but doses up to 4 gm/day may be needed[59] (usually in very obese patients)
      Duration: no consensus. Expert opinion: treat for up to 2 years
      Side effects: at high doses: acral paresthesias, nausea, metabolic acidosis, altered taste, renal calculi, drowsiness, diarrhea. Rare: Stevens-Johnson syndrome, toxic epidermal necrolysis, agranulocytosis.
      ✖ contraindications: allergy to sulfa or a history of renal calculi. Use under advisement of high-risk obstetrician during pregnancy due to claims of teratogenicity (which are disputed)
   b) topiramate (Topamax®): antiseizure medication with secondary inhibition of CA. ℞ start at 50 mg/d,[61] with weekly dose escalation by 25-50 mg/d up to 100-150 mg/d.[61] May help weight reduction by suppressing appetite
      Side effects: Similar to acetazolamide, but can be used in sulfa allergic patients, may reduce the efficacy of oral contraceptives, potentially teratogenic. Has significant adverse cognitive effects (see topiramate for seizures (p. 498)).
   c) methazolamide has been used in place of acetazolamide. May also be teratogenic

2. *furosemide* (Lasix®): used by some as an alternative, role is uncertain
   a) start: 160 mg per day in adults, adjust per symptoms and eye exam (not to CSF pressure)
   b) if ineffective, double (320 mg/day)
   c) monitor K^+ levels and supplement as needed

Shunts

The literature regarding shunt type is mainly observational and case series based. When considering shunting, complications (shunt infection or obstruction, shunt migration, low pressure H/A (p. 462), subdural hematoma (p. 464), mortality (low risk but not negligible)…) should be taken into account.

1. ventriculoperitoneal (VP) shunt is recommended due to reported lower revision rate[25,62]
   a) navigational techniques may facilitate ventricular catheter placement in the presence of small or slit-like ventricles (which are common in PTCS[63])
   b) a programmable valve with an antisiphon device should be considered to help manage and avoid low pressure H/A
2. lumbar shunt: usually lumboperitoneal; see insertion technique (p. 1830). Often more difficult in obese patients. May need a horizontal-vertical valve (p. 458) to prevent H/A from intracranial hypotension. Alternative: lumbopleural shunt. Visual loss has been reported in patients with functioning LP shunts.[64] Other potential complications include: back pain, radiculopathy, tonsillar herniation (secondary Chiari malformation) and scoliosis (p. 456). Contraindicated in the presence of lumbar spinal arachnoiditis
3. cisterna magna shunt: has been described, not commonly used. May shunt to vascular system

► **Important facts about shunts in PTCS**

- shunts are very effective for *acute* treatment of H/A in PTCS (95% have relief in the 1st month)[25]
- some patients will achieve long-term relief, however, at 3 years, ≈ 50% of PTCS patients will have recurrenc of severe H/A despite a working shunt[25]
- patients without papilledema had a higher rate of recurrence of H/A (75% by 3 years)[25]
- 80% of shunts require revision by 36 months[25]

Optic nerve sheath fenestration (ONSF)

See references.[65,66,67]

A surgical procedure usually performed by an ophthalmologist to create a window (fenestration) or series of slits in the optic nerve sheath immediately posterior to the globe. This may help by allowing egress of CSF thereby reducing pressure on the optic nerve within the sheath, and may also cause scarring that prevents Performed via medial transconjunctival approach (50%), a superomedial lid crease incision (31%) a lateral orbitotomy (10%).[68]

Generally better for protection of vision and reversal of papilledema than for other symptoms (fails to improve H/A in 33-50%[69]). No reported mortality. May reverse or stabilize visual deterioration[70] and sometimes (but not always) lowers ICP (by continued CSF filtration) and may protect the contralateral eye (if not, contralateral ONSF must be performed). Has succeeded in cases where visual loss progressed after LP shunting,[64] possibly due to poor communication between orbital and intracranial subarachnoid spaces. **Potential adverse effects:** includes pupillary dysfunction, peripapillary hemorrhage, chemosis, chorioretinal scarring,[71] diplopia (usually self-limited) from medial rectus disruption, worsening of vision (central retinal artery occlusion is a risk). Needs to be repeated in up to 6%.[10]

Endovascular procedures

Transverse sinus stenting. Transverse sinus (TVS) stenosis is a common epiphenomenon of increased ICP and in many cases may be a result of and not the cause of the increase. Endovascular placement of a stent across the stenosis to re-expand the lumen has been reported to improve symptoms after other measures fail. Stenting requires antiplatelet therapy afterwards (usually for > 6 months), which may preclude other intervention (e.g., shunting) if it fails. Most studies are observational and case series. Current guidelines consider the role of neurovascular stenting as not yet established[37]; however, since their publication there has been a recent trend to move to unilateral TVS stenting for PTCS patients with persistent increased ICP and papilledema who have failed to respond adequately to medical therapy who have bilateral TVS stenosis with an elevated TVS pressure gradient (a gradient > 8 mm Hg across the stenosis has been arbitrarily recommended,[72,73] some use 5 as the cutoff).[37,74]

In a series of 32 PTCS patients,[75] 90% had a pressure gradient > 8 mmHg, with bilateral TVS narrowing. Following stenting, papilledema was eliminated in 96% and 81% were able to discontinue acetazolamide. 6% had to have a repeat procedure.

Decompressive craniectomy

Usually subtemporal decompression, or less frequently suboccipital decompression.

Subtemporal decompression: older treatment advocated by Dandy. Fell out of favor (possibly because of risk of post-op seizures and painful bulging at decompression site), but may still have a place in the armamentarium[76] (e.g., patient with slit ventricles and in whom lumbar-peritoneal shunting is not feasible). Steps:

1. "silver-dollar size" craniectomies (approximately 1 inch = 25.4 mm) under the temporalis muscle to the floor of the middle fossa are made (usually bilaterally) through a linear incision. Kessler et al[76] used larger 6–8 cm diameter unilateral craniectomies; this larger cranietomy may explain their high incidence (62%) of H/A and tense bulging decompression site necessitating CSF diversion
2. the dura is opened
3. the brain is covered with an absorbable sponge (e.g., Gelfoam®)
4. the fascia and muscle are closed in a watertight fashion
5. a short course of antiseizure medications is used due to risk of post-op seizures

57.9.3 Guidelines for management

Adapted from the UK Guidelines[37] (there are currently no U.S. guidelines).

General measures

1. weight loss (p. 965): the only known disease-modifying intervention. Should be attempted in all patients with BMI ≥ 30 kg/m^2
2. ophthalmologic evaluation: at a minimum, dilated exam for papilledema and visual field assessment. Then, when possible, thorough ophthalmologic evaluation (p. 962) should be done
3. stop possible offending drugs: e.g., vitamin A
4. brain imaging within 24 hours:
   - MRI or CT: to rule-out surgical conditions including subdural hematoma, hydrocephalus, Chiari malformation, true mass (tumor, hemorrhage)…
   - venography: MRV or CTV. Primarily for "atypical patients" (patients who are male or not obese) or patients who have progression of visual deficit despite treatment
5. properly performed LP (p. 962) (after brain imaging rules out contraindications to LP (p. 1811), which include Chiari malformation, obstructive hydrocephalus…) or shunt tap (in patients with shunt)
   a) indications:
      1. patients who have not yet been diagnosed with PTCS
      2. patients with clinical signs of infection (meningitis, shunt infection…)
      3. patients with refractory H/A due to documented elevated CSF pressure (p. 968)
   b) objectives of LP/shunt tap:
      1. measure CSF pressure
      2. obtain CSF for analysis: routine labs. Also include CSF culture if clinical suspicion of infection
6. follow newly diagnosed patient at least two years with repeat imaging (e.g., MRI) to R/O occult tumor
7. see sections immediately below for guidelines pertaining to specific scenarios

For visual loss with PTCS

By definition of PTCS, these patients have papilledema. In addition to general measures (above):

1. ★ **fulminant PTCS**. Suggested definition: < 4 weeks between symptom onset to severe loss of acuity or visual field, and worsening of vision over a few days.[77] Severe visual is not always defined, but likely includes PMD (p. 589) more negative than about -7. Occurs in ≈ 2-3% of PTSC patients.[77] Necessitates rapid intervention to protect vision:
   a) immediate
      1. lumbar drain: when definitive treatment (shunting or ONSF) will not occur within 24 hrs, temporize by using a lumbar drain to decrease ICP
      2. start acetazolamide or topamax (see below)
   b) optic nerve sheath fenestration or CSF diversion (shunting or revision of existing shunt) ASAP. These measures work well in the short term
   c) start or continue efforts at weight loss to modify the underlying disease

Shunting may relieve both H/A and papilledema simultaneously. ONSF may be more effective in relieving visual problems (the failure rate may be lower than the shunt malfunction rate) but is not as good for the H/A.

2. mild *stable* visual loss (no immediate threat to vision)
   a) start or continue efforts at weight loss to modify the underlying disease
   b) consider medical therapy
      - acetazolamide (p. 965) plus low-sodium weight-reduction diet. Provides modest visual field improvement compared to diet alone in patients with mild visual loss,[78] and at 6 months improved QOL measures.[79] Caution re metabolic acidosis, kidney stones, pregnancy… (see acetazolamide (p. 965))

        or
      - topiramate (p. 965): may help by reducing CSF production (carbonic anhydrase effect) and by suppressing appetite which may aid weight loss
   c) evaluate H/A phenotype (including medication overuse H/A), treat accordingly
   d) ophthalmological follow-up: based on papilledema grade and visual field status as shown in ▶ Table 57.5
   e) shunt or ONSF for significant visual deterioration on follow-up

Table 57.5 Recommended ophthalmologic follow-up schedule[a] [37]

Papilledema grade	Visual field status			
	Normal	Abnormal & improving	Abnormal & stable	Abnormal & worsening
Atrophic[b]			4-6 mos	≤ 4 wks
Mild	6 mos	3-6 mos	3-4 mos	
Moderate	3-4 mos	1-3 mos	1-3 mos	≤ 2 wks
Severe			≤ 4 weeks	≤ 7 days

[a] once papilledema resolves, follow-up is not necessary except for asymptomatic patients who require longer follow-up since they will not be aware if there is recurrence

[b] atrophic papilledema: visible optic nerve head pallor due to nonviable optic nerve axons. Precludes diagnosis of papilledema

For H/A with PTCS and no visual loss (or mild/stable visual loss)

"Despite significant headache morbidity in IIH, there are no randomized controlled trials to guide headache management in IIH."[37] In addition to general measures (above):

1. rule-out overshunting (p. 462) in patients with shunts (low-pressure H/A, thickened meninges on imaging…). Consider revision if present
2. LP or shunt tap only for clinical suspicion of infection
3. a multidisciplinary approach involving a practitioner with expertise in H/A management is recommended to assess H/A phenotype (including medication overuse H/A) and to direct treatment specific for that phenotype
4. medication: judicious use of ***non-opioid*** medical therapy to treat H/A in the short-term (for the first few weeks) may help. Medication overuse headache (p. 960) (MOH) can occur with long-term use and is treated by elimination of overuse[80]
5. greater occipital nerve block: may be considered, but effectiveness is controversial
6. ✖ ***not*** recommended for H/A alone (without visual loss):
   - medication to ↓ ICP: acetazolamide has not been shown to be effective for H/A alone (see above)
   - CSF shunting or shunt revision*:[37] limited evidence of efficacy. 68% continue to have H/A at 6 months, and 79% at 2 years, 28% develop low pressure H/A.[81] Failure of shunting may be attributable to inadequate medical treatment of a migrainous component or medication overuse H/A
   - optic nerve sheath fenestration (ONSF)
   - serial LPs are not recommended for H/A alone[37]
   - neurovascular stenting is not recommended for H/A[37]

   * Shunting or shunt revision may be indicated for refractory H/A, and then only after elevated ICP is documented (e.g., on ICP monitoring) and preferably under advisement of a multidisciplinary team (neurologist, ophthalmologist, sleep medicine, and neurosurgeon)

For pseudotumor cerebri syndrome without papilledema (PTCSWOP)

For PTCSWOP (p. 958),

1. "risk of visual loss has not been identified and does not seem to develop over the disease course."[37] Caution: papilledema may not be reliably discerned if optic atrophy is present
2. counselling as appropriate for weight management (p. 965) as with PTCS
3. H/A should be managed as with PTCS (see above)
4. ✖ surgical intervention (shunting, shunt revision, or ONSF) to control increased ICP should not be considered unless advised by a multidisciplinary team

Asymptomatic PTCS patients

Treatment of asymptomatic PTCS patients is controversial and challenging as there is no reliable predictor for visual loss. Close follow-up with serial formal visual field evaluation is necessary. Intervention is recommended in unreliable patients, or whenever visual fields deteriorate. It is possible to lose vision without H/A or papilledema.

For PTCS in children and adolescents

1. may be seen with withdrawal of steroids used for asthma
2. search for and correction of underlying etiology (offending drugs listed above, hypercalcemia, cancer…)
3. acetazolamide has been used with success

For PTCS in pregnancy

1. women who first present with PTCS during pregnancy: resolution of PTCS following delivery is common
2. weight management to maintain weight gain that is appropriate for the gestational age of the fetus as recommended by the ACOG[82]
3. no specific mode of delivery should be recommended based on the diagnosis of PTCS
4. women who become pregnant during therapy:
   a) 1st trimester: observation, limitation of weight gain, serial LPs.
   ✖ Acetazolamide should be avoided because of teratogenicity in rodents
   b) 2nd & 3rd trimester: acetazolamide has been used safely, but involvement of high-risk obstetrician specialist is advised
   c) topiramate should not be used in pregnancy
5. if acute vision loss is threatened, serial lumbar punctures (p. 965) may be used to temporize until CSF diversion or ONSF can be performed

For pseudopapilledema

Pseudopapilledema (p. 588) (associated with drusen, etc.) in the absence of intracranial hypertension needs no intervention.[10] Reassurance and H/A management are recommended.

58 Tumors and Tumor-Like Lesions of the Skull

58.1 Skull tumors

58.1.1 General information

See Skull lesions (p. 1661) for differential diagnosis and evaluation (including non-neoplastic lesions). Considering only tumors, the differential diagnosis includes:

1. benign tumors
   a) osteoma: see below
   b) hemangioma: see below
   c) dermoid and epidermoid tumors: see below
   d) chondroma: occur mainly in conjunction with the basal synchondroses
   e) meningioma involving the skull
   f) aneurysmal bone cyst
2. malignant tumors: malignancy is suggested by a single large or multiple (> 6) small osteolytic lesions with margins that are ragged, undermined, and lacking sclerosis[1]
   a) bone metastases to the skull. Common ones include:
      - prostate
      - breast
      - lung
      - kidney
      - thyroid
      - lymphoma
      - multiple myeloma/plasmacytoma (p. 928)
      - direct extension of head and neck tumors, e.g., squamous cell carcinoma of the scalp
   b) chondrosarcoma
   c) osteogenic sarcoma
   d) fibrosarcoma

58.1.2 Osteoma

General information

Osteomas are the most common primary bone tumor of the calvaria. They are benign, slow-growing lesions that occur commonly in the cranial vault, mastoid and paranasal air sinuses, and the mandible. Lesions within air sinuses may present as recurrent sinusitis. More common in females, highest incidence is in 6th decade. Triad of Gardner's syndrome: multiple cranial osteomas (of calvaria, sinuses, and mandible), colonic polyposis, and soft-tissue tumors.

See Localized increased density or hyperostosis of the calvaria (p. 1664) for differential diagnosis.

Pathology

Consists of osteoid tissue within osteoblastic tissue, surrounded by reactive bone. Difficult to distinguish from fibrous dysplasia (p. 975).

Radiographic evaluation

Skull X-ray: round, sclerotic, well-demarcated, homogeneous dense projection. Usually arise from outer table of skull (inner table less common). May be compact or spongy (spongy osteoma may be radiolucent). Unlike meningiomas, diploë are preserved and vascular channels are not increased.

Osteomas are "hot" on nuclear bone scan.

Treatment

Asymptomatic lesions may simply be followed. Surgery may be considered for cosmetic reasons, or if pressure on adjacent tissues produces discomfort. Lesions involving only the outer table may be removed, leaving the inner table intact.

58.1.3 Hemangioma

General information

Comprise ≈ 7% of skull tumors.[1] These benign tumors commonly occur in the skull (discussed here) and spine (p. 992). Two types: cavernous (most common) and capillary (rare).

Radiographic evaluation

Skull X-ray: characteristically shows a circular lucency with honeycomb or trabecular pattern (seen in ≈ 50% of cases) or radial trabeculations producing a sunburst pattern (seen in ≈ 11% of cases).[1] Sclerotic margins are evident in only ≈ 33%.

CT: hypodense lesion with sclerotic spaced trabeculations. Nonenhancing.

Bone scan: typically hot.

Treatment

Accessible lesions may be cured by en bloc excision or curettage. The gross appearance is of a hard, blue-domed mass beneath the pericranium. Radiation may be considered for inaccessible tumors.

58.1.4 Epidermoid and dermoid tumors of the skull

General information

See also epidermoids and dermoids in general (p. 973).

Dermoids and epidermoids are benign inclusion cysts of ectoderm that may involve skull and underlying dural venous structures or brain. They may become infected. Primary skull involvement is rare and occurs when ectodermal rests are entrapped in the developing skull, which causes these tumors to arise within the diploë and expand both inner and outer tables. Because they are not neoplastic, they grow at a linear rate (instead of exponential). Usually midline.

Epidermoid tumors contain only the outer layer of skin, and are therefore lined with stratified squamous epithelium and the resultant byproduct, keratin.

Dermoid tumors contain all elements of skin including hair follicles (which may produce hair in the tumor) and dermal glands (sebaceous glands (apocrine) and sweat glands (eccrine)).[2]

Teratomas are true neoplasms and may also contain bone, cartilage, teeth, and nails.

Presentation

These lesions may present as a result of mass effect from continued growth.

They may rupture (more common with dermoids than epidermoids), and can cause chemical meningitis (from the irritating properties of fat and or keratin), or, if infected, bacterial meningitis.

Radiographic evaluation

1. skull X-ray: these osteolytic lesions have well-defined, sclerotic margins
2. some imaging is required to evaluate possible intracranial involvement
   a) CT: the lesions are hypodense (keratin contains fats), and non-enhancing
   b) MRI: like CSF they are low intensity on T1WI and high signal on T2WI, but unlike CSF they are high signal on DWI > MRI (p. 938)

Treatment

Treatment is surgical. Radiation and chemotherapy are not indicated.

When possible, the goal is to avoid rupture during removal in order to avoid chemical and/or bacterial meningitis.

Bone margins are curetted. Search must be made for a tract leading to the intracranial cavity which must be followed if found. Preparation for dural sinus repair must be made for lesions overlying the sagittal sinus (including torcular Herophili).

Endoscopic surgery may be an option for some skull base lesions.

58.1.5 Langerhans cell histiocytosis

Formerly called histiocytosis X (or eosinophilic granuloma, when solitary). May occur in the skull as a result of direct invasion of craniofacial bone and skull base, or from meninges (p. 846).

58.1.6 Squamous cell carcinoma of the scalp involving the skull

It is not unusual for plastic surgeons to request neurosurgical assistance in managing squamous cell carcinoma of the scalp that involves the calvaria over the convexity. For first time surgical intervention (i.e., non-recurrence) without resectable mass or frank invasion through the inner table of the bone, neurosurgical management usually involves burring down the outer table in the area of involvement until normal appearing bone is encountered, taking care not to penetrate the inner table.

58.2 Non-neoplastic skull lesions

58.2.1 General information

Includes:

1. osteopetrosis (p. 1689)
2. Paget's disease of the skull
3. hyperostosis frontalis interna (see below)
4. fibrous dysplasia (p. 975)

58.2.2 Hyperostosis frontalis interna

General information

See differential diagnosis (p. 1664). Hyperostosis frontalis interna (HFI) is a benign irregular nodular thickening of the inner table of the frontal bone that is almost always bilateral. The midline is spared at the insertion of the falx. Unilateral cases have been reported,[3] and in these cases one must R/O other etiologies such as meningioma, calcified epidural hematoma, osteoma, fibrous dysplasia, an epidural fibrous tumor,[4] or Paget's disease.

Epidemiology

The incidence of HFI in the general population is ≈ 1.4–5%.[3] HFI is more common in women (female: male ratio may be as high as 9:1) with an incidence of 15–72% in elderly women. A number of possible associated conditions have been described (most are unproven), the majority of which are metabolic, earning it the alias of metabolic craniopathy. Associated conditions include:

1. Morgagni's syndrome (AKA Morgagni-Stewart-Morel syndrome): headache, obesity, virilism, and neuropsychiatric disorders (including mental retardation)
2. endocrinologic abnormalities
   a) acromegaly (p. 870) [5] (elevated growth hormone levels)
   b) hyperprolactinemia[5]
3. metabolic abnormalities
   a) hyperphosphatemia
   b) obesity
4. diffuse idiopathic skeletal hyperostosis (DISH) (p. 1373)

Clinical

HFI may present without symptoms as an incidental finding on radiographic evaluation for other reasons. Many signs and symptoms have been attributed to HFI, including: hypertension, seizures, headache, cranial nerve deficits, dementia, irritability, depression, hysteria, fatigability, and mental dullness. The incidence of headache may be statistically higher in patients with HFI than in the general population.[6]

Evaluation

Blood tests to R/O some of the above noted conditions may be indicated in appropriate cases: check growth hormone, prolactin, phosphate, alkaline phosphatase (to R/O Paget's disease).

Plain skull X-ray shows thickening of the frontal bone with characteristic sparing of the midline. Spread to parietal and occipital bone occasionally occurs.

CT demonstrates the lesion, which usually causes 5–10 mm of bone thickening, but as much as 4 cm has been reported.

Bone scan: usually shows moderate uptake in HFI (generally not as intense as with bone mets). Also, indium-111 leukocyte scan (commonly used to detect occult infection) will show accumulation in HFI (a false positive).[7,8]

Treatment

In spite of a large number of published descriptive works in the medical literature, primarily in the early and mid-20th century, little has been written about treatment of cases where symptoms are suspected to be due to HFI. In one report, removal of the thickened bone was accomplished without evidence of dural adhesions, and with improvement in the presenting hysteria.[3]

Surgical technique

One technique described consists of using the craniotome to excise the thickened portion of the bone (a plain skull X-ray may be used to make a template), and then the thickened bone is thinned down with a high-speed drill, and the bone flap is then replaced. Alternatively, a cranioplasty with methylmethacrylate or custom-made implant fabricated using CT data may be performed.

58.2.3 Fibrous dysplasia

General information

Key concepts

- non-neoplastic condition where bone is replaced by expansile fibrous connective tissue
- malignant transformation to osteosarcoma or other sarcoma occurs in < 1%
- common sites of involvement: ribs, proximal femur, craniofacial bone
- associated endocrinopathies are common: includes precocious puberty or growth hormone excess
- may be monostotic, polyostotic, or part of McCune-Albright syndrome (triad: café au lait spots, endocrinopathy (e.g., precocious puberty) and polyostotic fibrous dyslpasia)
- common presentation: may be incidental, cosmetic, hearing loss, rarely visual loss
- treatment:
    - observation is often the best initial management. Prophylactic surgery for optic nerve compression is not justified due to the typical slow progression and the high risk of visual loss with surgery
    - medical therapy may include calcitonin, bisphosphonates, ? RANK ligand inhibitors
    - treat endocrinopathies (reduces morbidity including visual loss with GH excess)
    - ✖ XRT is not recommended

Fibrous dysplasia (FD) is a non-neoplastic benign condition in which normal bone is replaced by fibrous connective tissue and immature woven bone that is weaker than normal bone and tends to expand. Most lesions occur in the ribs, proximal femur or craniofacial bones (especially the maxilla). Frequent femoral neck fractures can lead to a varus deformity (so-called “shepherd’s crook deformity”)

Molecular genetics: FD is not heritable. It results from somatic activating mutations in the α subunit of the stimulatory G protein encoded by the GNAS locus at 20q13.2-q13.3.

Types of involvement

Localization of involvement

3 patterns of involvement

1. monostotic fibrous dysplasia (MFD): most common. The most frequent site of involvement is the zygomatic-maxillary complex
2. polyostotic fibrous dysplasia (PFD): 25% with this form have > 50% of the skeleton involved with associated fractures and skeletal deformities
3. PFD as part of McCune-Albright syndrome (and its variants). Triad:
    a) café au lait spots which tend to occur on one side of the midline and tend to be more jagged than those seen in neurofibromatosis (p. 638) and fewer in number

   b) endocrinopathy: including precocious puberty (primarily in females) and growth hormonesecretion
   c) polyostotic fibrous dysplasia (PFD)

Skull involvement occurs in 27% of MFD. In PFD and MAS, craniofacial involvement occurs in 90% of cases and the anterior skull base is involved inn > 95%.[9]

3 forms of fibrous dysplasia lesions

1. cystic (the lesions are not actually cysts in the strict sense): widening of the diplöe usually with thinning of the outer table and little involvement of the inner table. Typically occurs high in calvaria
2. sclerotic: usually involves skull base (especially sphenoid bone) and facial bones
3. mixed: appearance is similar to cystic type with patches of increased density within the lucent lesions

Epidemiology

True incidence is unknown since many cases are asymptomatic. FD constitutes ≈ 7% of benign bone lesions.[10] MFD is probably more common than PFD, but the actual ratio depends on the screening methodology. MAS is more common in females.

Clinical

Clinical manifestations of craniofacial fibrous dysplasia lesions include:

1. incidental finding (i.e., asymptomatic)
2. local pain or tenderness: the lesions are not tender, but overlying stretched periosteum may be. Associated aneurysmal bone cysts (ABCs) may be painful
3. local swelling (rarely: marked distortion resembling aneurysmal bone cyst)
4. changes due to facial deformity/asymmetry
   a) cosmetic: frontal bossing, hypertelorism
   b) orbital involvement may cause: proptosis, vertical dystopia (asymmetry in vertical alignment of the eyes), visual loss (p. 976)
   c) nasal congestion
   d) mandibular involvement: asymmetry which may produce malocclusion
5. may predispose to pathologic fractures when FD lesions occur in long bones
6. cranial nerve-related manifestations:
   a) hearing loss: temporal bone involvement may obliterate the external auditory canal or may restrict movement of middle ear ossicles. Temporal bone involvement occurs in > 70% of cases of craniofacial PFD and MAS and is uncommon in MFD[11]
   b) visual loss: an uncommon but recognized sequela of FD as a result of compression of the optic nerve in the optic canal, more common in children
   c) trigeminal neuralgia[12]
   d) facial nerve palsy: rare. Compression typically occurs within Fallopian canal and/or IAC
7. seizures: rare presentation
8. serum alkaline phosphatase is elevated in about 33%, calcium levels are normal
9. darkened hair pigmentation overlying skull lesions
10. spontaneous scalp hemorrhages
11. rarely associated with Cushing's syndrome, acromegaly

Evaluation

A major objective is to determine if the patient has a single lesion (MFD) or multiple lesions as in PFD or MAS.

1. history:
   - onset and nature of symptoms
   - rapidity of progression
   - history of pathologic fractures (clue for other FD lesions)
   - indications of endocrinopathies: age of menarche in females (R/O precious puberty), growth abnormalities (R/O growth hormone excess)
2. physical exam: look for and ask about skin discoloration (café-au-lait spots)
3. diagnostic studies:
   - skeletal survey (total body X-rays) or bone scan if additional lesions are suspected

- non-contrast head CT with thin cuts (▶ Fig. 58.1): characteristic ground glass appearance of craniofacial FD on X-rays and CT is due to the thin spicules of woven bone. With age, lesions morph into a mixed radio-dense/radio-lucent appearance. In prepubertal patients with PFD or MAS a homogeneous radio-dense appearance is more common.
- panorex and/or dental films when there is involvment around the teeth

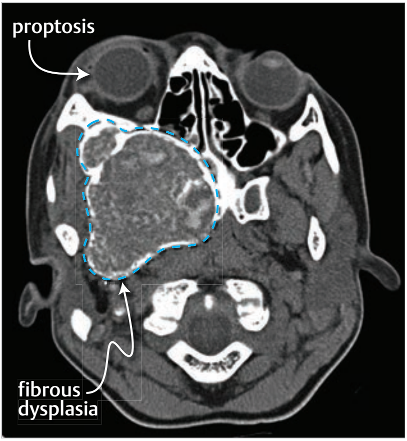

Fig. 58.1 Fibrous dysplasia of the right middle cranial fossa (outlined by *blue broken line*).
Image: axial CT scan, bone window.

Natural history

FD lesions are usually slowly progessive.

Rapid progression may occur:

- infrequently, in PFD or MAS prior to puberty. Progression usually slows when skeletal maturity is reached.
- malignant transformation: occurs in < 1% of cases.[11] Typically to osteosarcoma, but other sarcomas are possible (fibrosarcoma, chondrosarcoma…)
- associated expansile lesions:
  - aneurysmal bone cyst (ABC)
  - mucocele: when the ostium to a sinus becomes occluded by fibrous overgrowth
- osteomyelitis: often difficult to cure in the presence of FD

The most disfiguring and symptomatic lesions occur in patients with poorly controlled excess growth hormone (GH).[13] Therefore excess GH should be managed aggressively

Craniofacial FD may be categorized as[11]:

1. quiescent: no progression. Typically with smaller lesions
2. non-aggressive: slow growing
3. aggressive: rapid growth, associated pain, pathologic fractures, malignant transformation…

Management

Observation is often the best first management option. Delay surgery until skeletal maturity (around age 10–12 years) if possible.

Cure may be possible with smaller lesions in MFD but is unlikely with PFD or MAS. Local procedures (mostly orthopedic) are used for appendicular deformities or bone pain that is refractory to other treatment. Incompletely resected lesions are subject to regrowth.

Consult an endocrinologist if there is any suspicion of endocrinopathy.

Biopsy of an accessible lesion by the appropriate surgical specialist should be considered when the diagnosis is in doubt.[11] Bleeding may be brisk due to vascularity. Biopsy does not promote growth of the lesion. Histology does not predict biological behavior.

Quiescent craniofacial lesions without complaints of facial deformity may be monitored with annual evaluations which should include: patient reported symptoms, neurologic exam including sensory testing, photographs and facial CT for the first 2 visits and then less frequently based on prior CT results and clinical findings.

Non-aggressive or quiescent lesions producing bothersome facial disfigurement may be treated by a craniofacial surgeon. If practical, it is best to wait until the patient reaches skeletal maturity.

When optic canal involvement is documented, annual ophthalmological exams should be conducted. The diagnosis of optic neuropathy is made when there is a visual defect or if 2 out of 3 exams (contrast sensitivity, color vision and funduscopic exam) are abnormal. Optic neuropathy in FD is more common in patients with growth hormone excess.[13,14] Evidence suggest aggressive management of GH excess reduces the risk of optic neuropathy.

When there is temporal bone involvement, regular otolaryngology exams (including microscopy for EAC stenosis) should be performed to maintain patency of EAC (from bone, cerumen or the rare cholesteatoma). Annual audiology evaluations are recommended during periods of active lesion growth.

Pain is a common complaint, and is more prevalent in the lower extremities than with craniofacial involvement. It does not correlate with disease burden.

Calcitonin may be used for widespread lesions with bone pain and/or high serum alkaline phosphatase levels.

Bisphosphonates (e.g., alendronate, pamidronate or zoledronic acid): mixed results for craniofacial pain control and growth rate reduction in FD.

RANK ligand inhibitors e.g., denosumab: uncertain role in FD.[15]

✖ Radiation therapy is not recommended (risk of XRT induced tumors).

► **Neurosurgical involvement.** May be required for skull lesions producing refractory pain or neurologic symptoms or for rapidly growing associated lesions (e.g., ABC). Calvarial lesions may be treated with curettage and cranioplasty. Once the dysplastic bone is disconnected from the skull, the loss of vascular supply usually renders it inactive. Skull base lesions often require a multidisciplinary approach.

Acute visual deterioration associated with an expansile lesion near the optic canal should be treated with high-dose glucocorticoids and rapid surgical decompression.[14] However, vision is usually preserved despite optic canal narrowing with FD,[9] and visual loss may follow injudicious surgical intervention due to the intolerance of the optic nerve to surgical trauma. Rule out other possible explanations for visual loss before operating.

Image guidance may be helpful when drilling down exuberant bone to decompress the optic canal. Copious irrigation (e.g., with irrigating drill) is critical to avoid thermal damage. Endoscopic techniques may be useful adjuncts, but the distorted anatomy requires an experienced practitioner.

59 Tumors of the Spine and Spinal Cord

59.1 Spine tumors – general information

15% of primary CNS tumors are intraspinal (the intracranial:spinal ratio for astrocytomas is 10:1; for ependymomas it is 3–20:1).[1] There is disagreement over the prevalence, prognosis, and optimal treatment. Most primary CNS spinal tumors are benign (unlike the case with intracranial tumors). Most present by compression rather than invasion.[2]

59.2 Compartmental locations of spinal tumors

May be classified into 3 groups based on the compartment involved. Although metastases may be found in each area, they are most commonly extradural. Frequencies quoted below are from a general hospital, extradural lesions are less common in neurosurgical clinics because many of these tumors are managed by oncologists without requiring neurosurgical involvement.

1. extradural (ED) (55%): arise outside cord in vertebral bodies or epidural tissues
2. intradural extramedullary (ID-EM) (40%): arise in leptomeninges or roots. Primarily meningiomas and neurofibromas (together = 55% of ID-EM tumors)
3. intramedullary spinal cord tumors (IMSCT) (p. 984), 5%: arise in SC substance. Invade and destroy tracts and gray matter

► **Spinal lymphoma.** Lymphoma may occur in any of or all 3 compartments.

1. epidural
   a) metastatic or secondary lymphoma: the most common form of spinal lymphoma. Spinal involvement occurs in 0.1–10% of patients with non-Hodgkin's lymphoma
   b) primary spinal epidural non-Hodgkin's lymphoma: rare. Completely epidural with no bony involvement. The existence of this entity is controversial, and some investigators feel that it represents extension of undetected retroperitoneal or vertebral body lymphoma. May have a better prognosis than secondary lymphoma[3]
2. intramedullary
   a) secondary (p. 986) (metastatic)
   b) primary: very rare (see below)

59.3 Differential diagnosis: spine and spinal cord tumors

59.3.1 General information

See also Myelopathy (p. 1696) for a list including not only tumors but also *nonneoplastic* causes of spinal cord dysfunction (e.g., spinal meningeal cyst, epidural hematoma, transverse myelitis…).

59.3.2 Extradural spinal cord tumors (55%)

Arise in vertebral bodies or epidural tissues

1. metastatic: comprise the majority of ED tumors
   a) most are osteolytic (cause bony destruction): see Spinal epidural metastases (p. 921). Common ones include:
      - lymphoma: most cases represent spread of systemic disease (secondary lymphoma); some cases may be primary (see below)
      - lung
      - breast
      - prostate
   b) metastases that may be osteoblastic:
      - in men: prostate Ca is the most common
      - in women: breast Ca is the most common
2. primary spinal tumors (very rare)
   a) chordomas (p. 825)
   b) osteoid osteoma (p. 990)
   c) osteoblastoma (p. 990)
   d) **aneurysmal bone cyst (ABC):** an expansile tumor-like osteolytic lesion consisting of a highly vascular honeycomb of blood-filled cavities separated by connective tissue septa, surrounded by a

    thin cortical bone shell which may expand. Comprise 15% of spine tumors.[4] Etiology is controversial. May arise from preexisting tumor (including: osteoblastoma, giant cell tumor, fibrous dysplasia, chondrosarcoma) or following acute fracture. In the spine, there is a tendency to involve primarily the posterior elements. Peak incidence is in the second decade of life. Treatment usually consists of intralesional curettage. High recurrence rate (25–50%) if not completely excised
    e) chondrosarcoma: a malignant tumor of cartilage. Lobulated tumors with calcified areas
    f) osteochondroma (AKA chondroma AKA osteocartilaginous exostosis): benign tumors of bone that arise from mature hyaline cartilage. Most common during adolescence. An enchondroma is a similar tumor arising within the medullary cavity
    g) vertebral hemangioma (p. 992)
    h) **giant cell tumors (GCT)** of bone (p. 995) : AKA osteoclastoma
    i) giant cell (reparative) granuloma: AKA solid variant of ABC.[5] Related to GCT. Occurs primarily in mandible, maxilla, hands and feet, but there are case reports of spine involvement.[5,6] Not a true neoplasm—more of a reactive process. Treatment: curettage. Recurrence rate: 22–50%, treated with re-excision
    j) brown tumor of hyperparathyroidism
    k) osteogenic sarcoma: rare in spine
3. miscellaneous
    a) plasmacytoma (p. 931)
    b) multiple myeloma (p. 928)
    c) **unifocal Langerhans cell histiocytosis (LHC), formerly eosinophilic granuloma**: osteolytic defect with progressive vertebral collapse; LHC is one cause of **vertebra plana** (p. 1679) . C-spine is the most commonly affected region. Individual LHCs associated with systemic conditions (Letterer-Siwe or Hand-Schüller-Christian disease) are treated with biopsy and immobilization. Collapse or neurologic deficit from compression may require decompression and/or fusion. Low-dose XRT may also be effective[7,8]
    d) Ewing's sarcoma: aggressive malignant tumor with a peak incidence during the second decade of life. Spine mets are more common than primary spine lesions. Treatment is mostly palliative: radical excision followed by XRT (very radiosensitive) and chemotherapy[9]
    e) chloroma: focal infiltration of leukemic cells
    f) angiolipoma: ≈ 60 cases reported in literature
    g) neurofibromas (p. 982): most are intradural, but some are extradural, usually dilate neural foramen (dumbbell tumors)
    h) Masson's vegetant intravascular hemangioendothelioma (p. 961) [10]

59.3.3 Intradural extramedullary spinal cord tumors (40%)

1. meningiomas: usually intradural, but may be partly or, in 15%, wholly extradural; see below
2. neurofibromas: usually intradural, but may be partly or wholly extradural
3. many lipomas are extramedullary with intramedullary extension
4. miscellaneous: only ≈ 4% of spinal metastases involve this compartment

59.3.4 Intramedullary spinal cord tumors (5%)

1. astrocytoma (p. 985): 30%
2. ependymoma (p. 984): 30%, including myxopapillary ependymoma (p. 985)
3. miscellaneous: 30%, includes:
    a) malignant glioblastoma
    b) dermoid. In addition to the general population, dermoids present in a delayed fashion following ≈ 16% of myelomeningocele (MM) closures.[11] An iatrogenic etiology has been debated[12]; however, a case of a congenital dermoid in a newborn with MM[13] indicates that the origin is not always from incompletely excised dermal elements at the time of MM closure
    c) epidermoid
    d) teratoma
    e) lipoma
    f) hemangioblastoma (p. 986)
    g) neuroma (very rare intramedullary)
    h) syringomyelia (not neoplastic)
4. extremely rare tumors
    a) lymphoma
    b) oligodendroglioma
    c) cholesteatoma

   d) intramedullary metastases: comprises only ≈ 2% of spinal mets
   e) solitary fibrous tumors of the spinal cord: recognized in 1996. Probable mesenchymal origin. May also occur extramedullary (less common). Treatment is complete surgical excision. Prognosis is unclear[14]

59.4 Intradural extramedullary spinal cord tumors

59.4.1 Spinal meningiomas

See reference.[15]

Epidemiology

Peak age: 40–70 years. Female:male ratio = 4:1 overall, but the ratio is 1:1 in the lumbar region. 82% thoracic, 15% cervical, 2% lumbar. 90% are completely intradural, 5% are extradural, and 5% are both intra- and extradural. 68% are lateral to the spinal cord, 18% posterior, 15% anterior. Multiple spinal meningiomas occur rarely.

Clinical

Symptoms (▶ Table 59.1.)

Signs prior to surgery (only 1 of 174 patients was intact)[15]:

1. motor
   a) pyramidal signs only: 26%
   b) walks with aid: 41%
   c) antigravity strength: 17%
   d) flexion-extension with gravity removed: 6%
   e) paralysis: 9%
2. sensory
   a) radicular: 7%
   b) long tract: 90%
3. sphincter deficit: 51%

Table 59.1 Symptoms of spinal meningiomas

Symptom	At onset	At time of first surgery
local or radicular pain	42%	53%
motor deficits	33%	92%
sensory symptoms	25%	61%
sphincter disturbance		50%

Outcome

Recurrence rate with complete excision is 7% with a minimum of 6 years follow-up (relapses occurred from 4 to 17 years post-op).[15]

59.4.2 Spinal schwannomas

General information

Key concepts

- slow growing benign tumors
- most (75%) arise from the dorsal (sensory) rootlets
- early symptoms are often radicular
- recurrence is rare after total excision (except in neurofibromatosis)

Incidence: 0.3–0.4/100,000/yr. Most occur sporadically and are solitary, but they may also be associated with neurofibromatosis (p. 637), primarily type 2 (NF2), but can occur with type 1.

Configurations

Most are entirely intradural, but 8–32% may be completely extradural[16,17]; 1–19% are a combination, 6–23% are dumbbell, and 1% are intramedullary.

▶ **Dumbbell tumors.** Definition: tumors that develop an "hourglass" shape as a result of an anatomic barrier encountered during growth. Not all dumbbell tumors are schwannomas, e.g., neuroblastoma (p. 637). Most have a contiguous intraspinal, foraminal (usually narrower), and extraforaminal components (widening of the neural foramen is a characteristic finding, can be recognized even on plain films, and speaks to the longstanding benign nature of the lesion). The waist may also be due to a dural constriction.

Asazuma et al[18] classification system for dumbbell spinal schwannomas is shown in ▶ Fig. 59.1.

Type I tumors are intradural and extradural and are restricted to the spinal canal. The constriction occurs at the dura.

Type II are all extradural, and are subclassified as: IIa = do not extend beyond the neural foramen, IIb = inside spinal canal + paravertebral, IIc = foraminal + paravertebral.

Type IIIa are intradural and extradural foraminal, IIIb are intradural and extradural paravertebral.

Type IV are extradural and intravertebral. Type V are extradural and extralaminar with laminar invasion. Type VI show multidirectional bone erosion.

Craniocaudal spread: IF and TF designate the number of intervertebral foramina and transverse foramina involved, respectively (e.g., IF stage 2 = 2 foramens).

Schwannomas involving C1 & C2: May involve vertebral arteries and require additional caution.

Clinical

Patients typically present with local pain.

Neurologic deficits develop late. Tumors may cause radiculopathy (from nerve root compression), myelopathy (from spinal cord compression), radiculomyelopathy (from compression of both), or cauda equina syndrome (for tumors below conus medullaris).

Pathology

Composed of Antoni A (compact, interwoven bundles of long, spindly Schwann cells) and Antoni B tissue (sparse areas of Schwann cells in a loose eosinophilic matrix).

Surgical approaches

See reference.[19]

Posterior approaches: Types I, IIa, IIIa, some upper cervical IIIb, and some VI are generally amenable to a posterior approach. IIa and IIIa usually require total facetectomy for complete removal.[18] Reconstruction with instrumentation may be needed if substantial posterior disruption occurs.

Strategy for large tumors: a nerve stimulator can be used to identify a "safe zone" where the capsule can be incised without going through nerve tissue. Then the tumor is debulked internally. It is often not possible to separate tumor from nerve as the tumor passes into the neural foramen. Here it is not unusual to end up with a thin capsule of tumor attached to strands of nerve, and this typically results in satisfactory function.

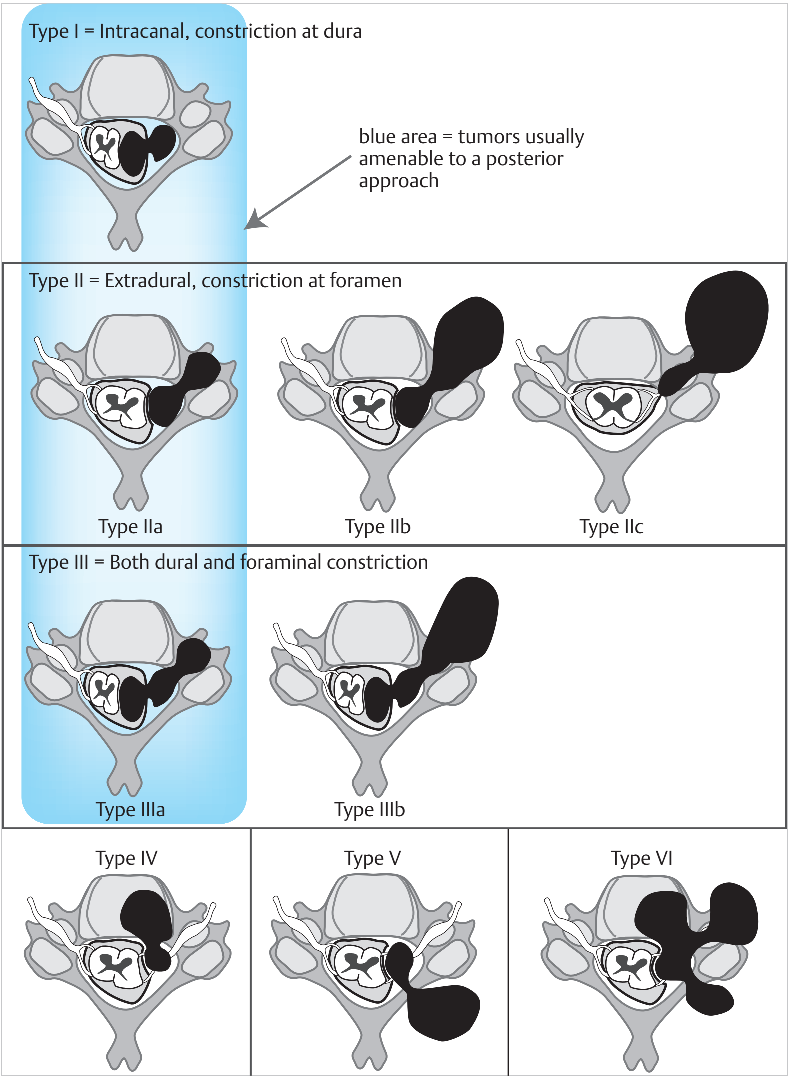
Anterior and combined anterior/posterior approaches: Asazuma et al[18] recommend a combined approach for Type IIb, IIc, and IIIb lesions where the extraforaminal extension is large (viz. beyond the vertebral arteries). Reconstruction with instrumentation was required for some tumors (≈ 10% of all patients treated) which were type IV (2 patients), IIIb (1 pt), and VI (1 pt).

Nerve sacrifice

It is usually possible to preserve some fascicles of the nerve root, although sometimes section of the entire nerve root is required. New deficits may not occur, especially with large tumors, since involved fascicles are often nonfunctional, and adjacent roots may compensate. The risk for motor deficit is higher for schwannomas than for neurofibromas, for cervical vs. lumbar tumors, and for cervical tumors with extradural extension.

Outcome

Recurrence is rare following gross total excision, except in the setting of NF2.



Type I = Intracanal, constriction at dura
blue area = tumors usually amenable to a posterior approach
Type II = Extradural, constriction at foramen
Type IIa
Type IIb
Type IIc
Type III = Both dural and foraminal constriction
Type IIIa
Type IIIb
Type IV
Type V
Type VI

Fig. 59.1 Classification of dumbbell spinal tumors. (Modified with permission from Asazuma T, Yoshiaki T, Hirofumi M, et al. Surgical strategy for cervical dumbbell tumors based on a three-dimensional classification. Spine 2003;29(1):E10–4.)

59.5 Intramedullary spinal cord tumors

59.5.1 Types of intramedullary spinal cord tumors

The following list excludes metastases (see below) and lipomas (of questionable neoplastic origin,[20] and most are actually extramedullary intradural, see below). **Note:** in pediatrics, astrocytoma and ependymoma constitute 90% of intramedullary spinal cord tumors (IMSCT).

1. astrocytoma (nonmalignant): 30% (the most common IMSCT outside the filum terminale[2]) tend to be eccentric
2. ependymoma: 30%, tend to be more central, more uniform dense enhancement
3. miscellaneous: 30%, including:
   a) malignant glioblastoma
   b) dermoid
   c) epidermoid (including iatrogenic from LP without stylet)[21,22]
   d) teratoma
   e) hemangioblastoma (see below)
   f) hemangioma
   g) neuroma (very rarely intramedullary)
   h) extremely rare tumors
      - primary lymphoma (only 6 case reports, all non-Hodgkin type[23])
      - oligodendroglioma, only 38 cases in world literature[24]
      - cholesteatoma
      - paraganglioma
      - primary spinal embryonal tumor (“spinal PNET”) (p. 744) [25]
      - pilomyxoid astrocytoma (p. 689)
      - metastasis

59.5.2 Differential diagnosis

Also see DDx for Myelopathy (p. 1696).

1. neoplasm (tumor): (see above for list). Enhancement: 91% enhance[26]; of the 9% that do not, most were astrocytomas, 1 was a subependymoma; enhancement did not correlate with grade
2. *nonneoplastic* lesions
   a) vascular lesions (e.g., AVM): serpiginous linear flow-void. Spinal angiography may be useful[2]
   b) demyelinating disease (e.g., multiple sclerosis):
      - usually does not extend > 2 vertebral levels
      - cord lesions in MS are most common in the cervical region
   c) inflammatory myelitis
   d) paraneoplastic myelopathy
   e) diseases causing pain over certain body segments (e.g., cholecystitis, pyelonephritis, intestinal pathology). To differentiate from these, look for dermatomal distribution, increase with Valsalva maneuver, and accompanying sensory and/or motor changes in LEs that suggest cord/radicular lesion. Radiographic studies are frequently required to differentiate
   f) diseases of vertebral structures, e.g., Paget’s disease, giant cell tumors of bone (p. 995), etc.

59.5.3 Specific types of intramedullary spinal cord tumors

Ependymoma

General information

Key concepts

- the most common glioma of lower cord, conus, and filum (most ependymomas in conus and filum are myxopapillary ependymomas). More common in adults
- evaluation: includes imaging the entire neuraxis (usually with enhanced MRI: cervical, thoracic, lumbar, and brain) because of potential for seeding through CSF
- associated cysts are common
- treatment: surgical excision (most are encapsulated)

See WHO diagnostic criteria (p. 732). The most common glioma of the lower spinal cord, conus and filum (see below). Slow-growing. Benign. Slight male predominance; slight peak in 3rd to 6th decade. Over 50% in filum, next most common location is cervical. Histologically: papillary, cellular, epithelial, or mixed (in filum, myxopapillary ependymoma is most common, see below). Cystic degeneration in 46%. May expand spinal canal in filum.[27] Usually encapsulated and minimally vascular (papillary: may be highly vascular; may cause SAH). Symptoms present > 1 yr prior to diagnosis in 82% of cases.[28]

Myxopapillary ependymoma

Myxopapillary ependymomas are a subtype of ependymoma that tend to occur at the conus medullaris, the filum terminale or cauda equina (► Fig. 59.2). They are WHO grade 1. Usually solitary. Histology: papillary, with microcystic vacuoles, mucosubstance; connective tissue. No anaplasia, but CSF dissemination occurs rarely (can seed intracranially following removal of spinal tumor[29]). Denovo intracranial lesions also occur rarely. Rare reports of systemic mets.[1] Outside the CNS, may occur in sacrococcygeal subcutaneous tissues from heterotopic rests of ependymal cells.[30]

Surgical removal of filum tumors consists of coagulating and dividing the filum terminale just above and below the lesion—see Distinguishing features of the filum terminale intraoperatively (p. 292)—and excising it in total. The filum is first cut *above* the lesion to prevent retraction upwards.

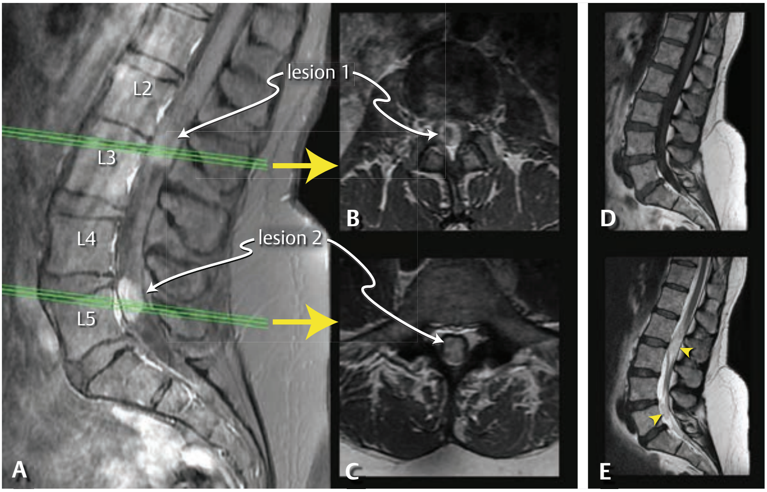


Fig. 59.2 Myxopapillary ependymoma. Two myxopapillary ependymomas of the lumbar spine.
Image: contrast T1 MRI, A: midline sagittal, B: axial slice through upper lesion located near the conus, C: axial slice through lower lesion located in the cauda equina. D: unenhanced sagittal T1 image, the lesions are isointense with their surroundings. E: lesions (*yellow arrowheads*) are fairly easily identified on this noncontrast T2WI sagittal image.

Astrocytoma

Uncommon in first year. Peak: 3rd–5th decade. Male:female = 1.5:1. The ratio of low-grade:high-grade = 3:1 in all ages.[27] Occurs at all levels, thoracic most common, then cervical. 38% are cystic; cyst fluid usually has high protein.

Dermoid and epidermoid

Epidermoids are rare before late childhood. Slight female predominance. Cervical and upper thoracic rare; conus common. Usually ID-EM, but conus/cauda equina may have IM component (completely IM lesions rare).

Lipoma

May occur in conjunction with spinal dysraphism, see Lipomyeloschisis (p. 284). The following considers lipomas that occur in the absence of spinal dysraphism.

Peak occurrence: 2nd, 3rd, and 5th decade. Technically hamartomas. No sex predominance. Usually ID-EM (a sub-type is truly IM and essentially replaces the cord[31]), cervicothoracic region is the most common location. NB: unlike other IMSCTs, most common symptom is ascending mono- or paraparesis (c.f. pain). Sphincter disturbance is common with low lesions. Local subcutaneous masses or dimples are frequent. Malis recommends early subtotal removal at about 1 year of age in asymptomatic patient.[31] Superficial extrasacral removal is inadequate, as patients then develop dense scarring intraspinally leading to fairly rapid severe neurological damage with poor salvageability even after the definitive procedure.

Hemangioblastoma

(▶ Fig. 59.3). Usually non-infiltrating, well demarcated, may have cystic caps. 80% of patients with spinal hemangioblastoma will have von Hippel-Lindau disease (p. 646). Cannot incise nor core because of vascularity. Requires microsurgical approach similar to AVM, possibly with intraoperative hypotension.

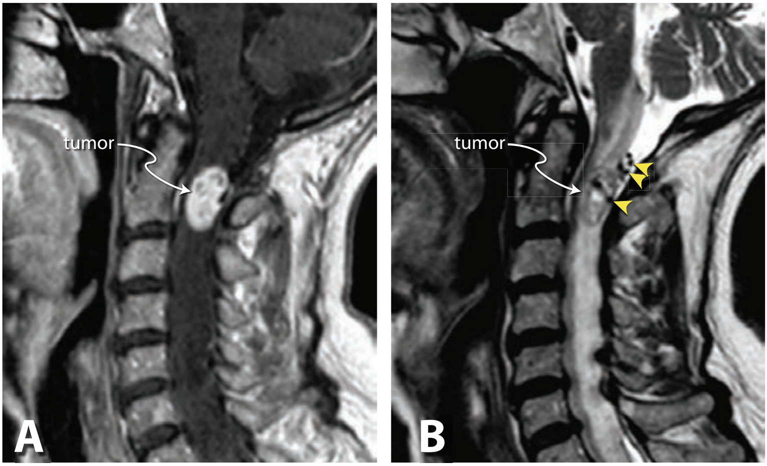

Fig. 59.3 Intramedullary hemangioblastoma of the cervical spinal cord.
Sagittal MRI. A: T1 with contrast. B: T2.
Flow voids appear dark on the T2 image, with several of them denoted by *yellow arrowheads*.

Metastases

Most spinal mets are extradural. Intramedullary metastases are rare,[32] accounting for 3.4% of symptomatic metastatic spinal cord lesions.[33] Primaries include: small-cell lung Ca,[34] breast Ca, malignant melanoma, lymphoma and colon Ca.[33,35] Ca rarely presents first as an intramedullary spinal met.

59.5.4 Presentation

1. pain: the most common complaint. Almost always present in filum tumors (exception: lipomas).[21] Possible pain patterns:
    a) radicular: increases with Valsalva maneuver and spine movement. Suspect SCT if dermatome is unusual for disc herniation
    b) local: stiff neck or back, Valsalva maneuver increases pain.
    ★ *Pain during recumbency ("nocturnal pain") is classic for SCT*

    - c) medullary (as in syrinx): oppressive, burning, dysesthetic, non-radicular, often bilateral, unaffected by Valsalva maneuver
2. motor disturbances
    - a) weakness is 2nd or 3rd most common complaint. Usually follows sensory symptoms temporally
    - b) children present most frequently with gait disturbances
    - c) syringomyelic syndrome: suggests IMSCT. Findings: UE segmental weakness, decreased DTR, dissociative anesthesia (see below)
    - d) long-tract involvement → clumsiness and ataxia (distinct from weakness)
    - e) atrophy, muscle twitches, fasciculations
3. non-painful sensory disturbances
    - a) dissociated sensory loss: decreased pain and temperature, preserved light touch, as in Brown-Séquard syndrome (p. 1135). There is disagreement whether this is common[2] or uncommon[36] in IMSCT. ± non-radicular dysesthesias (early), with upward extension[37]
    - b) paresthesias: either radicular or "medullary" distribution
4. sphincter disturbances
    - a) usually urogenital (anal less common) → difficulty evacuating, retention, incontinence, and impotence. Early in conus/cauda equina lesions, especially lipomas (pain not prominent)
    - b) sphincter dysfunction common in age < 1 yr due to frequency of lumbosacral lesions (dermoids, epidermoids, etc.)
5. miscellaneous symptoms:
    - a) scoliosis or torticollis
    - b) SAH
    - c) visible mass over spine

Time course of symptoms

Onset usually insidious, but abruptness occurs (benign lesions in children occasionally progress in hours). The onset is often erroneously attributed to coincidental injury. Temporal progression has been divided into 4 stages[38]:

1. pain only (neuralgic)
2. Brown-Séquard syndrome
3. incomplete transectional dysfunction
4. complete transectional dysfunction

Note: 78% (of 23) ependymomas, 74% (of 42) gliomas, all 7 dermoids, and 50% (of 8) lipomas reached the latter 2 stages before diagnosis (not affected by location in cross-sectional nor longitudinal dimension of SC (excludes conus lesions—more frequently diagnosed in 1st stage) (a pre-CT study)).

59.5.5 Diagnosis

It is usually difficult to distinguish IMSCT, ID-EM, and ED on clinical grounds.[2] Schwannomas often start with radicular symptoms that later progress to cord involvement. Most IMSCTs are located posteriorly in cord, which may cause sensory findings to predominate early.[20]

Diagnostic studies

MRI: mainstay of diagnosis. Ependymomas enhance intensely and are often associated with hemorrhage and cysts. Cord edema may mimic a cyst.

Plain radiographs: vertebral body destruction, enlarged intervertebral foramina, or increases in interpedicular distances suggests ED SCT.

Lumbar puncture: Elevated protein is the most common abnormality[1] seen in ≈ 95%. The reported range with primary IMSCTs is 50–2,240 mg%. Glucose is normal except with meningeal tumor. SCT can cause complete block, indicated by:

- Froin's syndrome: clotting (due to fibrinogen) and xanthochromia of CSF
- Queckenstedt's test (failure of jugular vein compression to increase CSF pressure, which it normally does in the absence of block)
- barrier to flow of myelographic contrast media

Myelography (p. 925): classically shows fusiform cord widening (may be normal early). Distinct from ED tumors, which produce hourglass deformity (with incomplete block) or paintbrush effect (with complete block), or ID-EM tumors, which produce a capping effect with a sharp cutoff (meniscus sign).

CT: some IMSCTs enhance with IV contrast. Myelo-CT distinguishes IMSCT from ID-EM (poor in differentiating IMSCT subtypes).

Spinal angiography: rarely indicated, except in hemangioblastoma (may be suspected on myelography or MRI by linear serpiginous structures). MRI often obviates this test.

59.5.6 Management

General information

Asymptomatic lesions may be followed since there is significant risk of neurologic deficit with surgery. For symptomatic lesions, surgery should be performed as soon as possible (generally not as an emergency) after diagnosis since surgical results correlate with the preoperative neurologic condition, and it makes no sense to follow the patient as they develop progressive neurologic deficit[39] (some of which may be irreversible).

Astrocytomas: For low grade lesions, if a plane can be developed between the tumor and spinal cord (when it can, it usually consists of a thin gliotic layer traversed by small blood vessels and adhesions[20]), an attempt at total excision is an option.[40] For high-grade astrocytomas or for low-grade astrocytomas without a plane of separation, biopsy alone or biopsy plus limited excision is recommended.[40]

For high-grade lesions, post-op XRT (± chemotherapy) is recommended.[40] XRT is not supported following radical resection of low grade gliomas.[40]

Ependymomas: Gross total removal should be attempted. XRT is not recommended following gross total removal.[40]

59.5.7 Technical surgical considerations

Key concepts

In the surgical removal of IMSCT

- in almost all cases, IMSCTs should be debulked from within using ultrasonic aspirator or laser (to minimize manipulation of neural tissue), and no attempt should be made initially to develop a plane between tumor and spinal cord (even for ependymoma, which of the 3 most common IMSCTs is the only one that actually has such a plane)
- ★ the key to removing IMSCTs is knowing when to stop. If MEPs or D-waves are being monitored, it is suggested that tumor removal should be discontinued if the amplitudes drop to ≤ 50% of baseline

1. position: usually prone, well padded and also securely taped to avoid undesirable movement if MEP monitoring is to be used. Other options include: lateral oblique, sitting
2. if a cystic component is suspected, partial aspiration with a 25 Ga needle once the spinal cord is exposed will decrease the pressure (do not try to completely aspirate the contents because that can make it more difficult to locate the tumor).[41] If the cyst forms a “cap” at either end of the tumor, the dura does not need to be opened over the cyst, since drainage can be accomplished with removal of tumor
3. adjunctive options include:
   a) electrophysiologic monitoring (p. 989)
   b) intraoperative ultrasound: also controversial,[42] favored by some experts. Astrocytomas are usually isoechoic with spinal cord, whereas ependymomas are usually hyperechoic
4. a myelotomy is performed either in the midline or just to one side of the dorsal midline to avoid the posteromedian vein. Alternatively, if the tumor is known to be very superficial off the midline (which may be confirmed by ultrasound), entry may be made there. Tumors may cause distortion and displacement of the midline—look for dorsal root entry zones on both sides to identify the midline as the midpoint between root entry zones
5. 6–0 silk sutures may be placed through the pial edge to gently retract the spinal cord open. Standard sized (i.e., non-micro) bayonet forceps can be used to gently spread tissues
6. copious irrigation is used whenever bipolar cautery is employed on the tumor/spinal cord in order to minimize transference of heat to the spinal cord. Monopolar cautery should not be used[41]

7. either laser or ultrasonic aspiration (USA) is used to debulk tumor from within until the glial-tumor interface is reached. Charring from laser may make it more difficult to recognize the glial-tumor interface than USA, and the laser tends to be slower when debulking larger tumors
8. watertight dural closure is critical

▶ **Electrophysiologic monitoring.** Intraoperative electrophysiologic monitoring (SSEP and motor evoked potentials [MEPs][43] and D-waves) is an aid in determining when to stop.

SSEPs almost always degrade with the initial myelotomy and do not correlate well with motor outcome[44] (which is critical),[42,45] and postoperative motor deficit may occur in spite of unaltered intraoperative SSEPs.[43,44] Conversely, SSEPs may be lost without motor deficit.

MEPs are useful, but since they can only be obtained intermittently they do not give real-time warning of a developing problem, and they often cause violent muscle contractions which can be disruptive to delicate surgery. There is a risk of seizures with transcranial MEPs, however none of 322 monitored patients undergoing *spinal cord* surgery had a seizure.[46]

Direct waves (D-waves): a single transcranial stimulus of 80-100 mA of 0.5-1 mS duration with a frequency 0.5-2 Hz produces a response that can be recorded by an electrode in the epidural or subdural space of the spinal cord.[47] They may be monitored continuously and since they do not need averaging they can alert the surgeon immediately when deterioration starts to occur.[48] They can determine the level of a deficit by moving the electrode to diffeerent levels, but they cannot determine laterality and cannot be used below T12 (due to too few corticospinal tract fibers) or in children less than ≈ 4 years age (due to incomplete maturation of motor pathways).[48] Deterioration to < 50% of baseline is highly correlated with severe post-op deficit.

59.5.8 Prognosis

No well-designed studies give long term functional results with microsurgery, laser, and radiotherapy. Better results occur with lesser initial deficits.[20] Recurrence depends on totality of removal, and on growth pattern of the specific tumor.

Ependymoma: total extirpation improves functional outcome, and myxopapillary ependymomas fare better than the "classic" type.[28] Best functional outcome occurs with modest initial deficits, symptoms < 2 years duration,[49] and total removal. Survival is independent of extent of excision.

Astrocytomas: radical removal is rarely possible (a cleavage plane is unusual even with a microscope). Long term functional results are poorer than with ependymomas. There is 50% recurrence rate in 4–5 yrs.

59.6 Primary bone tumors of the spine

59.6.1 General information

Types of tumors.

1. metastatic: the most common malignancy of spine
   a) common osteolytic metastatic tumors (p. 921) include:
      - lung
      - breast
      - prostate
      - lymphoma: most cases represent spread of systemic disease (secondary lymphoma); however, some may be primary (p. 979)
      - plasmacytoma (p. 928)
      - multiple myeloma (p. 928)
      - Langerhans cell histiocytosis: see differentiating features (p. 980)
   b) metastases that may be osteoblastic:
      - in men: prostate Ca is the most common
      - in women: breast Ca is the most common
   c) Ewing's sarcoma (p. 980)
   d) chloroma: focal infiltration of leukemic cells
2. primary spinal tumors (very rare)
   a) benign
      - vertebral hemangioma (p. 980)
      - osteoid osteoma (p. 990)
      - osteoblastoma (p. 990)
      - aneurysmal bone cyst (p. 979): cavity of highly vascular honeycomb surrounded by a thin cortical shell which may expand
      - osteochondroma (chondroma) (p. 980)

  - giant cell tumors of bone (p. 995): AKA osteoclastoma. Almost always benign with pseudo-malignant behavior

b) malignant
  - chondrosarcoma (p. 980)
  - chordomas (p. 825)
  - osteogenic sarcoma: rare in spine

59.6.2 Osteoid osteoma and osteoblastoma

General information

Key concepts

- both are benign bone tumors
- histologically identical, differentiation depends on size (≤ 1 cm = osteoid osteoma, > 1 cm = osteoblastoma)
- can occur in the spine and may cause neurologic symptoms (esp. osteoblastoma)
- high cure rate with complete excision

Two types of benign osteoblastic lesions of bone: osteoid osteoma (OO) and benign osteoblastoma (BOB), see ▶ Table 59.2. They are indistinguishable histologically, and must be differentiated based on size and behavior.

Characteristically cause night pain and pain relieved by aspirin (see Clinical below).

Table 59.2 Comparison of osteoid osteoma and benign osteoblastoma[50]

	Osteoid osteoma	Benign osteoblastoma
percent of primary bone tumors	3.2%	
percent of primary vertebral tumors	1.4%	
percent that occur in spine	10%	35%
size limitations	≤ 1 cm	> 1 cm
growth pattern	confined, self limiting	more extensive, may extend into spinal canal
potential for malignant change?	no	rare
location within spine (83 patients)		
• % in cervical spine	27%	25%
• % in thoracic spine		35%
• % in lumbar region	59%	35%
location within vertebra (81 patients)		
• lamina only	33%	16%
• pedicle only	15%	32%
• articular facet only	19%	0
• vertebral body (VB) only	7%	5%
• transverse process only	6%	8%
• spinous process	5%	5%
• > 1 element of neural arch	6%	19%
• combined posterior elements & VB	0	11%

Osteoblastoma is a rare, benign, locally recurrent tumor with a predilection for spine that may rarely undergo sarcomatous change (to osteosarcoma,[51] only a handful of known cases of this). More vascular than OO.[52]

Differential diagnosis

Lesions with similar symptoms and increased uptake on radionuclide bone scan:

1. benign osteoblastoma

2. osteoid osteoma: more pronounced sclerosis of adjacent bone than BOB
3. osteogenic sarcoma: rare in spine
4. aneurysmal bone cyst (p. 979): typically trabeculae in central, lucent region
5. unilateral pedicle/laminar necrosis

Clinical

See ▶ Table 59.3 for signs and symptoms. Tenderness confined to vicinity of the lesion occurs in ≈ 60%. 28% of patients with BOB presented with myelopathy. OO presented with neurologic deficit in only 22%.

Table 59.3 Signs and symptoms in 82 patients[50]

Finding	Osteoid osteoma	Benign osteoblastoma
pain on presentation	100%	100%
pain increased by motion	49%	74%
pain increased by Valsalva	17%	36%
nocturnal pain	46%	36%
pain relieved by aspirin	40%	25%
radicular pain	50%	44%
scoliosis	66%	36%
neurologic abnormalities	22%	54%
myelopathy	0	28%
weakness	12%	51%
atrophy	9%	15%

Evaluation

Bone scans are a very sensitive means for detecting these lesions. Once localized, CT or MRI may better define the lesion in that region.

Caution regarding needle biopsy: if the lesion turns out to be osteosarcoma, the contaminated needle tract can result in worse prognosis.

Osteoid osteoma

Radiolucent area with or without surrounding density, often isolated to pedicle or facet. May not show up on tomograms.

Osteoblastoma

Most are expansile, destructive lesions, with 17% having moderate sclerosis. 31% have areas of ↑ density, 20% surrounded by calcified shell. Often a contralateral spondylolysis.[51]

Treatment

In order to obtain a cure, these lesions must be *completely* excised. The role of radiation therapy is poorly defined in these lesions, but is probably ineffective.[51]

Osteoid osteoma

Cortical bone may be hardened and thickened, with granulomatous mass in underlying cavity.

Osteoblastoma

Hemorrhagic, friable, red to purple mass well circumscribed from adjacent bone. Complete excision → complete pain relief in 93%. Curettage only → pain relief, with more likely recurrence. Recurrence rate with total excision is ≈ 10%.

59.6.3 Osteosarcoma

The most common primary bone cancer. More common in children, usually occurring near the ends of long bones, but also in the mandible, pelvis, and rarely in the spine.[53] Spinal osteosarcoma usually occurs in the lumbosacral region in males in their 40s, sometimes arising from areas of osteoblastoma or Paget's disease. If a percutaneous biopsy reveals osteosarcoma, the contaminated needle tract can increase the difficulty of subsequent surgery. Poor prognosis, median survival = 10 months.[53]

59.6.4 Vertebral hemangioma

General information

Key concepts

- the most common primary spine tumor
- benign, but a small number behave aggressively
- rarely symptomatic (< 1.2%), symptoms typically from compression fracture, and, rarely, neural compression from bone expansion or soft tissue mass
- MRI: small lesions are hyperintense on T1WI and T2WI. Larger ones may be hypointense. CT or X-ray: striations (corduroy pattern) or "honeycomb" or polka dot pattern. Bone scan: usually do not have increased uptake
- treatment: incidental lesions require no treatment or routine follow-up. Biopsy when mets or malignancy are a strong consideration. Treatment options (when indicated): XRT, embolization, vertebroplasty (better than kyphoplasty), surgery

Vertebral hemangiomas (VH), AKA spinal hemangioma, cavernous hemangioma (of the vertebral body), or hemangiomatous angioma. Benign lesions of the spine. The most common primary tumor of the spine (10–12% of primary spinal bone tumors). Estimated incidence: 9–12%,[54,55] with a 10-12% prevalence in the general population.[54] 70% are solitary, 30% are multiple (up to 5 levels may be involved, often noncontiguous). Lumbar and lower thoracic spine are the most common locations; cervical and sacral lesions are rare. Lesions involve only the vertebral bodies in ≈ 25%, posterior spinal arch in ≈ 25%, and both areas in ≈ 50%. Rarely, aggressive hemangiomas may compromise neural structures (▶ Fig. 59.7).

Occasional cases of purely extradural lesions have been described.[56] Intramedullary spinal cord lesions are even less common.[57] Typically found in post-pubertal females.

Malignant degeneration does not occur. Mature thin-walled blood vessels of varying sizes replace normal marrow, producing hypertrophic sclerotic bony trabeculations oriented in a rostral-caudal direction in one of two forms: cavernous (venous) or capillary (difference in subtype carries no prognostic significance).

Presentation

1. incidental (i.e., asymptomatic) lesions
2. symptomatic: only 0.9–1.2% are symptomatic. There may be a hormonal influence (unproven) that may cause symptoms to increase with pregnancy (could also be due to increased blood volume and/or venous pressure)[58] or to vary with the menstrual cycle and may explain why symptoms rarely occur before puberty
   a) pain: occasionally VH may present with pain localized to the level of involvement with no radiculopathy. However, pain is more often due to other pathology (compression fracture, herniated disc, spinal stenosis…) rather than the VH itself
   b) progressive neurologic deficit: this occurs rarely, and usually takes the form of thoracic myelopathy. Deficit may be caused by the following mechanisms
      - subperiosteal (epidural) growth of tumor into the spinal canal
      - expansion of the bone (cortical "blistering") with widening of the pedicles and lamina producing a "bony" spinal stenosis
      - compression by vessels feeding or draining the lesion
      - compression fracture of the involved vertebra (very rare)[59]
      - spontaneous hemorrhage producing spinal epidural hematoma[60] (also very rare)
      - spinal cord ischemia due to "steal"

Imaging

Typical imaging features of VH are shown in ▶ Table 59.4.[61]

Table 59.4 Typical features of VH[61]

Typical features of VH include:
1. lesion limited primarily to vertebral body
2. vertical striation/honeycomb appearance/polka-dot sign on CT
3. hypointense on T1 and hyperintense on T2 MRI
4. enhancement on contrast MRI
5. restriction to 1 vertebral level, and when soft tissue mass invades the spinal canal, the soft tissue mass is < 1 vertebral body in length

Plain X-rays: classically show coarse vertically oriented striations (corduroy pattern) or a "honeycomb" appearance. At least ≈ one-third of the VB must be involved to produce these findings on plain X-ray (see ▶ Fig. 59.4 for demonstration of this finding on sagittal CT).

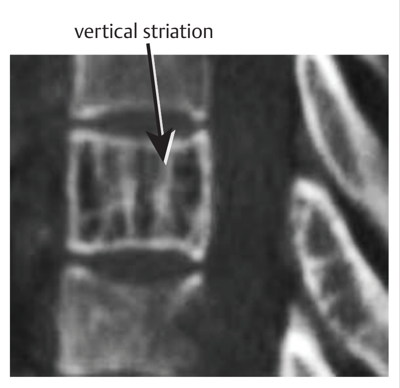

Fig. 59.4 Vertebral hemangioma.
Image: sagittal CT, bone window. Note the vertical striations ("corduroy pattern").

Bone scan: findings on multiphase^{99}Tx-MDP bone scintigraphy and PET scan are highly variable and are therefore not helpful.[62] If the lesion is "cold" (does not light up), it is likely not a metastasis.

MRI: small hemangiomas are focal, round, and hyperintense on T1WI and T2WI (▶ Fig. 59.5). More extensive lesions can be hypointense. MRI may help distinguish lesions that tend not to evolve (mottled increased signal on T1WI and T2WI, possibly due to adipose tissue) from those that tend to be symptomatic (isointense on T1WI, hyperintense on T2WI). Axial MRI may show "salt & pepper" appearance. VHs enhance due to high vascularity.

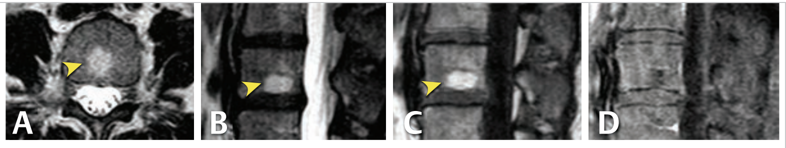

Fig. 59.5 Small round vertebral hemangioma (*yellow arrowheads*).
Image: MRI scans, A: axial T2, B:sagittal T2, C: sagittal T1, D: sagittal T1 with contrast (note lack of enhancement of the lesion).

CT: diagnostic procedure of choice for the bony involvement. Sagittal images may show vertical striations representing thickened trabeculae (▶ Fig. 59.4) while axial images show multiple high density dots within the bone ("Polka-dot sign"[63]) representing cross-sections through the trabeculae (▶ Fig. 59.6). NB: similar-appearing features may be seen in osteoporosis.

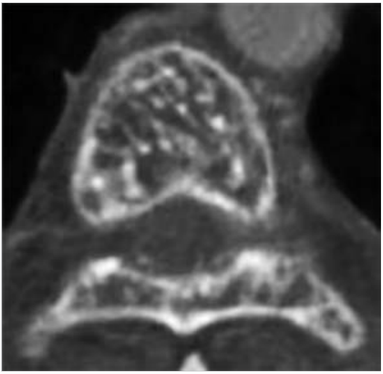

Fig. 59.6 Large vertebral hemangioma.
Image: axial CT bone window demonstrating "polka-dot sign."

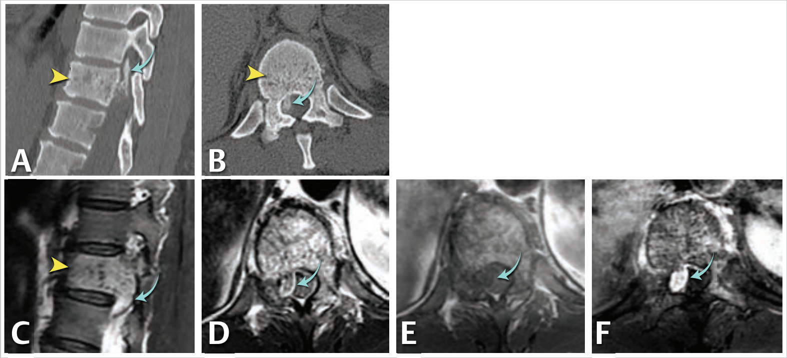

Fig. 59.7 Aggressive vertebral hemangioma.
Image: CT scan, A: sagittal through left side of spinal canal, B: axial.
MRI, C: sagittal T2 through left side of spinal canal, D: axial T2, E: axial T1, F: axial T1 + contrast.
Note the mottling of the VBs (*yellow arrowheads*), the extension of the lesion into the spinal canal (*curved blue arrow*), and the intense contrast enhancement.

Management

Management guidelines:

1. asymptomatic VH with typical features (▶ Table 59.4) without concern for malignancy: no treatment or routine follow-up is required[54,61]
2. biopsy: may be indicated in cases where malignancy (including metastases) is a concern or when there are atypical features on imaging (see typical features, ▶ Table 59.4).[61] In spite of their highly vascular nature, the risk of bleeding complications with CT guided biopsy is extremely low. An alternative to biopsy would be serial imaging, but the literature is sparse on this topic
3. those presenting with pain or neurologic deficit
    a) **radiation therapy** : VH are radiosensitive and undergo sclerotic obliteration. With aggressive VH, there is a risk of vertebral collapse following XRT[64]
        1. as a stand-alone treatment: for lesions causing pain without neuro deficit, XRT provided complete relief in 60-87.5%, and partial relief in nearly all.[65,66] Improvement in pain may be delayed up to years.
        With signs/symptoms of mild myelopathy (e.g. ASIA impairment scale ▶ Table 68.13 group D), some studies have shown clinical improvement with XRT. One review recommended a median total dose of 34 Gy, with a median single doses of 2.0 Gy.[66] Radiographic evidence of response may[66] or may not[54] occur

    2. as an adjunct following incomplete resection to decrease recurrence.[67] Total dosage should be ≤ 40 Gy to reduce the risk of radiation myelopathy

b) **embolization**: can provide immediate relief of pain, and may be used alone[68] or as a pre-op surgical adjunct to reduce operative blood loss. Risks: spinal cord infarction if major radicular artery—e.g., artery of Adamkiewicz (p. 87)—is embolized, and it may increase the risk of future fracture (not statistically significant). The decision whether to embolize pre-op is up to the surgeon[68,69,70,71]

c) **vertebroplasty** (p. 1212): has been used for painful VH or following XRT. May be better than kyphoplasty for VH because kyphoplasty destroys the trabecular bone, but no direct comparisons have been made. May be performed at the same time as CT-guided biopsy.[72,73] Not known to be effective for VH with neurologic deficit, but may be used as an adjunct to surgery[74,75]

d) **surgery**: generally regarded as the primary treatment for VH producing severe or rapidly progressive neurologic deficit, or for painful lesions that fail to respond to above measures. Recurrence rate is low (see below) and resolution of symptoms is high. When needed, surgery can stabilize the spine with fusion. Surgery may be discussed with the patient as an option for treatment of VH presenting only with pain if the comparative risk profile is preferred over the other options above, especially for lesions with high risk of instability

Surgical treatment

For surgical indications, see above. Recommendations for surgical management are shown in ▶ Table 59.5.

Intralesional resection results in a low recurrence rate (3% with 3.9 years mean follow-up) (i.e., the increased risk with en bloc resection is not warranted),[76] and resolution of symptoms is high. Pre-operative embolization is a viable option.

Major risks of surgery: blood loss, destabilization of the spine requiring fusion, neurologic deficit (during surgery, or postoperatively usually from epidural hematoma).

With subtotal resection, recurrence rate is 20-30% at 2 years, which was decreased to 7% using post-op XRT.[54,69] Surgery often requires fusion due to the common involvement of the anterior and middle columns of the thoracic or lumbar spine.[69,76,77,78]

Table 59.5 Recommendations for surgical management of VH[a] [54]

VH involvement	Approach	Post-op XRT?
posterior elements only	radical excision via posterior approach	not for total excision
VB involvement with anterior canal compression (with or without ST in canal)	anterior corpectomy with strut graft	
VB involved but no expansion, ST in lateral canal	laminectomy with removal of soft-tissue	follow serial CT, give XRT if VB expansion or ST expansion
extensive involvement of anterior and posterior vertebral elements with circumferential bone expansion, no ST compression	laminectomy	either XRT, or close follow-up with CT and XRT for ST recurrence or progressive VB expansion
extensive anterior and posterior involvement with ST in anterior canal	anterior corpectomy with strut graft	

[a] abbreviations: XRT = radiation treatment; ST = soft-tissue component of VH; VB = vertebral body.

59.6.5 Giant cell tumors of bone

AKA osteoclastoma (cells arise from osteoclasts). In the same general category as aneurysmal bone cysts. Typically arise in adolescence. Most common in knees and wrists. Those that come to the attention of the neurosurgeon generally arise in the skull (especially the skull base, and in particular the sphenoid bone), or in the vertebral column (≈ 4% occur in sacrum).

Pathology

Lytic with bony collapse. Almost always benign with pseudomalignant behavior (recurrence is common, and pulmonary mets can occur).

Evaluation

Soft tissues are best evaluated with MRI. Spine CT is critical to assess degree of bony destruction and for surgical planning purposes.

Work-up includes chest CT because of possibility of pulmonary mets.

Treatment

Intratumoral curettage, possibly aided by pre-op embolization. Recurrence rate with this treatment (even if resection is subtotal) is only ≈ 20%. Role of XRT is controversial[7] because of the possibility of malignant degeneration (therefore use XRT only for non-resectable recurrence).

Osteoclast inhibiting drugs have met with some success following subtotal resection:

1. bisphosphonates: e.g., pamidronate (p. 1364)
2. RANKL inhibitors: e.g., denosumab (Prolia®) (p. 926))

For gross residual disease after resection, re-resection is a consideration.

Cryosurgery with liquid nitrogen has been employed in long bones. Its use is limited in neurosurgical cases because of risk of injury to adjacent neural structures (brain, spinal cord) and cryotherapy induced fractures, although it has been described for use in the sacrum.[79]

Close follow-up is required due to propensity for recurrence. MRI or CT initially q 3 months is suggested.

XIV

60 Head Trauma – General Information, Grading, Initial Management

60.1 Head trauma – general information

60.1.1 Introduction

56–60% of patients with GCS score ≤ 8 have 1 or more other organ system injured.[1] 25% have "surgical" lesions. There is a 4–5% incidence of associated spine fractures with significant head injury (mostly C1 to C3).

When a detailed history is unavailable, remember: the loss of consciousness may have *preceded* (and possibly have caused) the trauma. Therefore, maintain an index of suspicion for e.g., aneurysmal SAH, hypoglycemia, etc. in the differential diagnosis of the causes of trauma and associated coma.

Brain injury from trauma results from two distinct processes:

1. primary brain injury: occurs at time of trauma (cortical contusions, lacerations, bone fragmentation, diffuse axonal injury, and brainstem contusion)
2. secondary injury: develops subsequent to the initial injury. Includes injuries from intracranial hematomas, edema, hypoxemia, ischemia (primarily due to elevated intracranial pressure (ICP) and/or shock), vasospasm

Since impact damage cannot be influenced by the treating neurosurgeon, intense interest has focused on reducing secondary injuries, which requires good general medical care and an understanding of intracranial pressure (p. 1036).

60.1.2 Delayed deterioration

≈ 15% of patients who do not initially exhibit signs of significant brain injury may deteriorate in a delayed fashion, sometimes referred to as patients who "talk and deteriorate," or when more lethal, patient who "talk and die."[2] Etiologies:

1. ≈ 75% will exhibit an intracranial hematoma
   a) may be present on initial evaluation and can then worsen
   b) may develop in a delayed fashion
      - delayed epidural hematoma (EDH) (p. 1075)
      - delayed subdural hematoma (SDH) (p. 1081)
      - delayed traumatic contusions (p. 1072)
2. posttraumatic diffuse cerebral edema (p. 1026)
3. hydrocephalus
4. tension pneumocephalus
5. seizures
6. metabolic abnormalities, includes:
   a) hyponatremia
   b) hypoxia: etiologies include pneumothorax, MI, CHF…
   c) hepatic encephalopathy
   d) hypoglycemia: including insulin reaction
   e) adrenal insufficiency
   f) drug or alcohol withdrawal
7. vascular events
   a) dural sinus thrombosis (p. 1594)
   b) carotid (or rarely, vertebral) artery dissection (p. 1578)
   c) SAH: due to rupture of aneurysm (spontaneous or posttraumatic) or carotid-cavernous fistula (CCF) (p. 1519)
   d) cerebral embolism: including fat embolism syndrome (p. 1013)
8. meningitis
9. hypotension (shock)

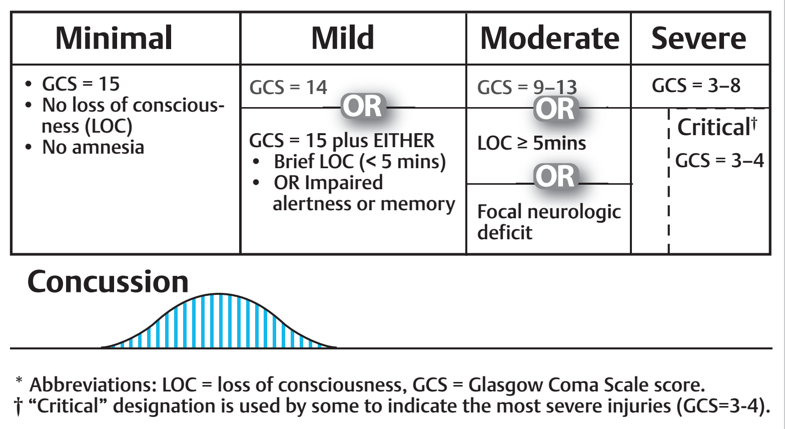
60.2 Grading

Despite many (valid) criticisms, the initial post-resuscitation Glasgow Coma Scale (GCS) score (▶ Table 18.1) remains the most widely used and perhaps best replicated scale employed for the assessment of head trauma. Problems with this type of scale include that it is an ordinal scale that is non parametric (i.e., does not represent precise measurements of discrete quantities), it is non-linear, and it is not an interval scale, so that for example, a decrease of 2 points in one parameter is not necessarily equal to a decrease in 2 points of another.[3] Thus, performing mathematical manipulations (e.g., adding components, or calculating mean values), while often done, is not statistically sound.[4]

▶ **Stratification.** There are a number of schemes to stratify the severity of head injury. Any such categorization is arbitrary and will be imperfect. A simple system based only on GCS score is as follows:

- GCS 14–15 = mild
- GCS 9–13 = moderate
- GCS ≤ 8 = severe

More elaborate systems (e.g., ▶ Fig. 60.1 [3]) may incorporate factors in addition to the GCS.



* Abbreviations: LOC = loss of consciousness, GCS = Glasgow Coma Scale score.
† "Critical" designation is used by some to indicate the most severe injuries (GCS=3-4).

Fig. 60.1 Sample stratification scheme for head injury severity.[3]

60.3 Transfer of trauma patients

It is sometimes necessary for a neurosurgeon to accept a trauma patient in transfer from another institution that is not equipped to handle major neurologic injuries, or to transfer patients to other facilities for a variety of reasons. ▶ Table 60.1 lists factors that should be assessed and stabilized (if

Table 60.1 Factors to assess in head injured patients

Clinical concern	Items to check	Steps to remedy
hypoxia or hypoventilation	ABG, respiratory rate	intubate any patient who has hypercarbia, hypoxemia, or is not localizing
hypotension or hypertension	BP, Hgb/Hct	transfuse patients with significant loss of blood volume
anemia	Hgb/Hct	transfuse patients with significant anemia
seizures	electrolytes, ASM levels	correct hyponatremia or hypoglycemia; administer ASMs when appropriate[a]
infection or hyperthermia	WBC, temperature	LP if meningitis is possible and no contraindications (p. 1811)
spinal stability	spine X-rays	spine immobilization (spine board, cervical collar & sandbags…); patients with locked facets should be reduced if possible before transfer

[a] see Seizures (p. 480), as well as Posttraumatic seizures (p. 504)

possible) prior to transfer. These items should also be evaluated in trauma patients about whom a neurosurgeon is consulted in his or her own E/R, as well as in patients with other CNS abnormalities besides trauma (e.g., SAH).

60.4 Management in E/R

60.4.1 General measures

Blood pressure and oxygenation

Practice guideline: BP and oxygenation

Level II[5]: monitor BP and avoid hypotension (SBP < 90 mm Hg)
Level III[5]: monitor oxygenation and avoid hypoxia ($PaO_2 < 60$ mm Hg or O_2 saturation < 90%)

Hypotension

Hypotension (shock) is rarely attributable to head injury except:

- in terminal stages (i.e., with dysfunction of medulla and cardiovascular collapse)
- where enough blood has been lost from scalp wounds to cause hypovolemia (exsanguination)
- in infancy, where enough blood can be lost intracranially or into the subgaleal space to cause shock

Hypotension (defined as a single SBP < 90 mm Hg) doubles mortality, hypoxia (apnea or cyanosis in the field, or $PaO_2 < 60$ mm Hg on ABG) also increases mortality,[6] and the combination of both triples mortality and increases the risk of bad outcome. SBP < 90 mm Hg may impair CBF and exacerbate brain injury and should be avoided (p. 1050).

Early use of paralytics and sedation (prior to ICP monitoring)

Practice guideline: Early sedation and paralysis

Level III[7]: sedation and neuromuscular blockade (NMB) can be helpful for transporting the head-injured patient, but they interfere with the neuro exam
Level III[7]: NMB should be used when sedation alone is inadequate

The routine use of sedatives and paralytics in neurotrauma patients may lead to a higher incidence of pneumonia, longer ICU stays, and possibly sepsis.[8] These agents also impair neurologic assessment.[7,9] Use should therefore be reserved for cases with clinical evidence of intracranial hypertension (see ▶ Table 60.2), for intubation, or where use is necessary for transport or to permit evaluation of the patient (e.g., to get a combative patient to hold still for a CT scan).[10]

Table 60.2 Clinical signs of IC-HTN[a]

1. pupillary dilatation (unilateral or bilateral)
2. asymmetric pupillary reaction to light
3. decerebrate or decorticate posturing (usually contralateral to blown[b] pupil)
4. progressive deterioration of the neurologic exam not attributable to extracranial factors

[a] Items 1–3 represent clinical signs of herniation. The most convincing clinical evidence of IC-HTN is the witnessed evolution of 1 or more of these signs. IC-HTN may produce a bulging fontanelle in an infant.
[b] "blown pupil": fixed & dilated pupil

Intubation and hyperventilation

Indications for *intubation* in trauma; also see **Practice guideline: Intubation – indications** (p. 1003):

1. depressed level of consciousness (patient cannot protect airway): usually GCS ≤ 7
2. need for hyperventilation (HPV): see below
3. severe maxillofacial trauma: patency of airway tenuous or concern for inability to maintain patency with further tissue swelling and/or bleeding
4. need for pharmacologic paralysis for evaluation or management

Practice guideline: Intubation—indications

Level III[11]: secure the airway (usually by endotracheal intubation) in patients with GCS ≤ 8 who are unable to maintain their airway or who remain hypoxic despite supplemental O_2

Cautions regarding intubation:

1. if basal skull fracture through cribriform plate is possible, avoid nasotracheal intubation (to avoid intracranial entry of tube). Use orotracheal intubation
2. prevents assessment of patient's ability to verbalize[9] e.g., for determining Glasgow Coma Scale score. This ability should be noted (none, unintelligible, inappropriate, confused, or oriented) prior to intubation
3. risk of pneumonia: see **Practice guideline: Antibiotics for intubation** (p. 1003) regarding antibiotics

Practice guideline: Antibiotics for intubation

Level II[12]: periprocedural antibiotics for endotracheal intubation reduce the risk of pneumonia, but do not alter length of stay or mortality

Hyperventilation (HPV)

Practice guideline: Early/prophylactic hyperventilation

Level II[13]: prophylactic hyperventilation ($PaCO_2 \leq 25$ mm Hg) is not recommended

Level III

- hyperventilation (HPV) before ICP monitoring is established should be reserved as a temporizing measure[13] for patients with signs of transtentorial herniation (see ▶ Table 60.2) or progressive neurologic deterioration not attributable to extracranial causes[7]
- HPV should be avoided during the first 24 hrs after TBI (when CBF is often dangerously decreased)[13]

1. since HPV may exacerbate cerebral ischemia, **HPV should not be used prophylactically** (p. 1052)
2. prior to ICP monitoring, HPV should only be used briefly when CT or clinical signs of IC-HTN are present[10] (see ▶ Table 60.2 for clinical signs)
   a) when appropriate indications are met: HPV to $PaCO_2 = 30–35$ *mm* Hg
   b) HPV should not be used to the point that $PaCO_2 < 30$ mm Hg (this further reduces CBF but does not necessarily reduce ICP)
3. acute alkalosis increases protein binding of calcium (decreases ionized Ca^{++}). Patients being *hyperventilated* may develop ionized hypocalcemia with tetany (despite normal total [Ca])

Mannitol in E/R

Practice guideline: Early use of mannitol

Level III[7,14]: the use of mannitol before ICP monitoring is established should be reserved for patients who are adequately volume-resuscitated with signs of transtentorial herniation (see ▶ Table 60.2) or progressive neurologic deterioration not attributable to extracranial causes

Indications in E/R, see also more details (p. 1053):

1. evidence of intracranial hypertension (see ▶ Table 60.2)
2. evidence of mass effect (focal deficit, e.g., hemiparesis)
3. sudden deterioration prior to CT (including pupillary dilatation)
4. after CT, if a lesion that is associated with increased ICP is identified
5. after CT, if going to O.R.
6. to assess "salvageability": in patient with no evidence of brainstem function, look for return of brainstem reflexes

Contraindications:

1. prophylactic administration is *not* recommended due to its volume-depleting effect. Use only for appropriate indications (see above)
2. hypotension or hypovolemia: hypotension can negatively influence outcome.[10] Therefore, when intracranial hypertension (IC-HTN) is present, first utilize sedation and/or paralysis, and CSF drainage. If further measures are needed, fluid resuscitate the patient before administering mannitol. Use hyperventilation in hypovolemic patients until mannitol can be given
3. relative contraindication: mannitol may slightly impede normal coagulation
4. CHF: before causing diuresis, mannitol transiently increases intravascular volume. Use with caution in CHF, may need to pre-treat with furosemide (Lasix®)

℞: bolus with 0.25–1 gm/kg over < 20 min (for average adult: ≈ 350 ml of 20% solution). Peak effect occurs in ≈ 20 minutes (p. 1053) (for follow-up dosing).

Prophylactic antiseizure medications (ASMs)

Practice guideline: Prophylactic antiseizure medications after TBI

Level II[15,16,17]: prophylactic phenytoin, carbamazepine, phenobarbital, or valproate[18] do not prevent late PTS

Level II: ASMs[17] (e.g., phenytoin, valproate, or carbamazepine[15,16,18]) may be used to decrease the incidence of early PTS (within 7 days of TBI) in patients at high risk of seizures after TBI (see ▶ Table 60.3); however, this does not improve outcome

Routine use of prophylactic antiseizure medications (ASMs) in traumatic brain injury (TBI) is ineffective in preventing the late development of posttraumatic seizures (PTS) i.e., epilepsy, and has been shown to not be useful except in certain circumstances.[15,16]

Table 60.3 Conditions with increased risk of posttraumatic seizures

1. acute subdural, epidural, or intracerebral hematoma (SDH, EDH or ICH)
2. open-depressed skull fracture with parenchymal injury
3. seizure within the first 24 hrs after injury
4. Glasgow Coma Scale score < 10
5. penetrating brain injury
6. history of significant alcohol abuse
7. ± cortical (hemorrhagic) contusion on CT

See details on using (p. 506) and discontinuing (p. 506) prophylactic ASMs following TBI. ▶ Table 60.3 reiterates the markers for patients at increased risk of early PTSs.

60.4.2 Neurosurgical exam in trauma

General information

It is not possible to outline a physical exam that is universally applicable. Major trauma must be assessed rapidly, often under chaotic circumstances, and must be individualized based on patient's medical stability, type of injury, degree of combativeness, use of pharmacologic paralytics (p. 1002), the needs of other caregivers attending to other organ injuries, the need to triage in the event of multiple patients requiring simultaneous attention…

The following describes some features that should be assessed under certain circumstances with the understanding that this *must be individualized*. This addresses only craniospinal injuries, and assumes that general systemic injuries (internal bleeding, myocardial and/or pulmonary contusion…) as well as orthopedic injuries (long bone and pelvic fractures…) will be treated by other members of a "trauma team." Although organized here in outline form, the most efficient order of examination is usually dictated by circumstances unique to each situation.

General physical condition (oriented towards neuro assessment)

1. visual inspection of cranium:
   a) evidence of basal skull fracture (p. 1064):
      - raccoon's eyes (AKA Panda bear sign): periorbital ecchymoses
      - Battle's sign: postauricular ecchymoses (around mastoid air sinuses)
      - CSF rhinorrhea/otorrhea (p. 418)
      - hemotympanum or laceration of external auditory canal

   b) check for facial fractures
      - Le Fort fractures (p. 1067): palpate for instability of facial bones, including zygomatic arch
      - orbital rim fracture: palpable step-off

   c) periorbital edema, proptosis
2. cranio-cervical auscultation
   a) auscultate over carotid arteries: bruit may indicate carotid dissection
   b) auscultate over globe of eye: bruit may indicate traumatic carotid-cavernous fistula CCF; see Carotid-cavernous fistula (p. 1519)
3. physical signs of trauma to spine: bruising, deformity
4. evidence of seizure: single, multiple, or continuing (status epilepticus)

Neurologic exam

1. cranial nerve exam
   a) optic nerve function (p. 1014)
      - if conscious: serial quantitation of vision in each eye is important.[19] A Rosenbaum near vision card is ideal (see inside back cover), otherwise use any printed material. If patient cannot see this, check if they can count fingers. Failing this, check for hand motion vision and lastly light perception. Children may develop transient cortical blindness lasting 1–2 days, usually after a blow to the back of the head
      - if unconscious: check for afferent pupillary defect (p. 592), best demonstrated with swinging flashlight test (p. 591). Indicates possible optic nerve injury
      - funduscopic exam: check for papilledema, pre-retinal hemorrhages, retinal detachment, or retinal abnormalities suggestive of anterior optic nerve injury. If a detailed exam is required, pharmacologic dilatation with mydriatics (p. 593) may be employed; however, this precludes pupillary exam for a variable period of time, and should be undertaken advisedly

   b) pupil: size in ambient light; reaction to light (direct & consensual)
   c) VII: check for peripheral VII palsy (p. 1064) (facial asymmetry of unilateral upper and lower facial muscles)
   d) VI: abducens palsy (p. 598) following trauma may occur as a result of ↑ ICP or with clival fractures (p. 1065)

2. level of consciousness/mental status
   a) Glasgow coma scale for quantitating level of consciousness in poorly responsive patient (see ▶ Table 18.1)
   b) check orientation in patient able to communicate
3. motor exam (assesses motor tracts from motor cortex through spinal cord)
   a) if patient is cooperative: check motor strength in all 4 extremities
   b) if uncooperative: check for appropriate movement of all 4 extremities to noxious stimulus (differentiate voluntary movement from posturing or stereotypical spinal cord reflex). This also assesses sensation in an unresponsive patient
   c) if any doubt about integrity of spinal cord: also check "resting" tone of anal sphincter on rectal exam, evaluate voluntary sphincter contraction if patient can cooperate, check anal wink with pinprick, and assess bulbocavernosus reflex (p. 1130) (see Neurological assessment, for details)
4. sensory exam
   a) cooperative patient:
      - check pinprick on trunk and in all 4 extremities, touch on major dermatomes (C4, C6, C7, C8, T4, T6, T10, L2, L4, L5, S1, sacrococcygeal)
      - check posterior column function: joint position sense of LEs
   b) uncooperative patient: check for central response to noxious stimulus (e.g., grimace, vocalization…, as opposed to flexion-withdrawal, which could be a spinal cord mediated reflex)
5. reflexes
   a) muscle stretch ("deep tendon") reflexes if patient is not thrashing: e.g., preserved reflex indicates that a flaccid limb is due to CNS injury and not nerve root injury (and vice versa)
   b) check plantar reflex for upgoing toes (Babinski sign)
   c) in suspected spinal cord injury: the anal wink and bulbocavernosus reflex are checked on the rectal exam (see above)

60.5 Radiographic evaluation of TBI in the E/R

60.5.1 General information

An unenhanced (i.e., non-contrast) CT scan of the head usually suffices for patients seen in the emergency department presenting after TBI or with a new neurologic deficit. Enhanced CT or MRI may be appropriate after the unenhanced CT in some circumstances, but are not usually required emergently (exceptions include: suspected ischemic stroke, significant brain edema on non-contrast CT suggesting a neoplasm that cannot be demonstrated without contrast).

Other tests: angiography may be needed acutely in certain circumstances, primarily in penetrating head trauma. Skull X-rays are usually inadequate for primary evaluation, but may be helpful in certain situations, for example with some retained foreign bodies.

Spine imaging: victims of TBI are often at risk for concomitant spine injuries. Spine imaging is covered in brief below and in detail under Spine Trauma.

See also special considerations in concussion (p. 1023).

60.5.2 Indications for initial brain CT

▶ **Initial imaging inconcussion** (p. 1019) **or mild TBI.** There is not uniform agreement about when to obtain an admitting imaging study (usually a noncontrast head CT scan) with mild TBI and concussion. Some recommendations for adults are provided below. For patients ≤ 16 years see Pediatric head injuries (p. 1099). Also see Initial imaging for moderate to severe TBI (p. 1008) for indications for CT in severe TBI and for specific conditions excluded from the mTBI guidelines (e.g., penetrating skull trauma).

The American College of Emergency Physicians (ACEP) guidelines (p. 1007) [20] for initial imaging for mTBI in patients ≥ 16 years age is based on previously published rules (including the Canadian CT Head Rule (p. 1007) for GCS = 13-15, and the New Orleans Criteria (▶ Table 60.5) for GCS = 15, which are included below for completeness since they are validated and in common use). The ACEP guidelines have not been validated.

Practice guideline: initial head CT with mTBI (ACEP policy)

Noncontrast head CT for patients ≥ 16 years age with GCS = 14-15 following non-penetrating TBI are indicated only if one or more of the following is present

Level I[20]: For patients with LOC or posttraumatic amnesia

- headache
- vomiting
- age > 60 years
- intoxication (alcohol or drugs)
- short-term memory deficits
- physical signs of trauma above the clavicle
- posttraumatic seizure
- GCS < 15
- focal neurologic deficit
- coagulopathy (including anticoagulants/antiplatelet drugs)*

Level II[20]: For patients without LOC or posttraumatic amnesia

- focal neurologic deficit
- vomiting
- severe headache
- age ≥ 65 years
- signs of basal skull fracture (includes hemotympanum, "raccoon's eyes" (p. 1065), CSF rhinorrhea or otorrhea, Battle's sign (p. 1065))
- GCS < 15
- coagulopathy (including anticoagulants/antiplatelet drugs)*
- dangerous mechanism of injury: pedestrian hit by motor vehicle, ejection from automobile, fall from height > 3 feet or > 5 stairs

*data regarding the risk of adverse outcome in anticoagulated patients after mTBI is limited and of low quality[21]

Canadian CT Head Rule (CCTHR) for mild TBI (GCS = 13-15) (▶ Table 60.4)[22] is a validated[23] decision rule that may be used to determine if an initial head CT is indicated for mild TBI (Glasgow Coma Scale score (GCS) = 13-15) in patients ≥ 16 years age who have a witnessed loss of consciousness, amnesia or confusion after a TBI who do not have exclusionary criteria listed in the table footnote.

★ The CCTHR is 100% sensitive for injuries requiring neurosurgical intervention.[23]

Table 60.4 Canadian CT Head Rule (CCTHR)[22]

Head CT is indicated for patients ≥ 16 years age with GCS = 13-15 from witnessed TBI, only if one or more of any of the following are present*:

High-risk criteria ("CT is mandatory"[22])(presence of any 1 often requires neurosurgical intervention)

- GCS < 15 at 2 hours post injury
- suspected open or depressed skull fracture
- signs of basal skull fracture (includes hemotympanum, "raccoon's eyes" (p. 1065), CSF rhinorrhea or otorrhea, Battle's sign (p. 1065))
- 2 or more episodes of vomiting
- age ≥ 65 years

Medium risk criteria (presence of any 2 often have clinically important findings on CT)

- amnesia before injury > 30 minutes
- dangerous mechanism of injury: pedestrian hit by motor vehicle, ejection from automobile, fall from height > 3 feet or > 5 stairs

* exclusionary criteria for the CCTHR (i.e., these patients were not studied): age < 16, coagulopathy including anticoagulants/antiplatelet drugs, seizure, penetrating skull trauma, focal neurologic deficit, unstable vital signs, return for reassessment of the same injury, pregnancy.
NB: intoxication (drugs or alcohol) reduces the sensitivity of the CCTHR to 70%[24]

New Orleans Criteria (NOC) for head CT(▶ Table 60.5)[25] may be used for GCS = 15. It may be more sensitive than the CCTHR for showing clinically significant CT findings (99% vs. 87.3%), but it is less specific (5.6% vs. 39.7%).

Table 60.5 New Orleans Criteria[25] for head CT scan

Head CT scan is indicated for patients with TBI and GCS = 15 only if one or more of the following are present:
1. headache 2. vomiting 3. age ≥ 60 years 4. drug or alcohol intoxication 5. persistent anterograde amnesia (short-term memory deficits) 6. visible trauma above the clavicle 7. seizure

▶ **Indications for imaging in pediatrics with mTBI[26] :** See Pediatric head injuries (p. 1099).

▶ **Initial imaging for moderate to severe TBI**

1. brain CT is indicated in TBI with any of the following risk factors:
   a) GCS ≤ 14
   b) unresponsiveness
   c) depressed level of consciousness not clearly due to EtOH, drugs, metabolic abnormalities, postictal state, etc.
   d) coagulopathy including anticoagulants/antiplatelet drugs
   e) seizure
   f) penetrating skull trauma
   g) focal neurologic deficit
   h) unstable vital signs
   i) polytrauma
   j) suspected nonaccidental trauma (i.e., child abuse)
   k) patients intoxicated with alcohol or other drugs (due to unrealiability of clinical assessment)
   l) deteriorating neurologic status
2. assessment prior to general anesthesia for other procedures (during which neurologic exam cannot be followed in order to detect delayed deterioration)

60.5.3 CT findings in trauma

The main emergent conditions to rule out (and brief descriptions):

1. blood (hemorrhages or hematomas):
   a) extra-axial blood: surgical lesions are usually ≥ 1 cm maximal thickness
      - epidural hematoma (EDH) (p. 1072): usually biconvex and often due to arterial bleeding. Unlike SDH, EDH may cross dural barriers such as the the falx or tentorium (▶ Fig. 64.2)
      - subdural hematoma (SDH) (p. 1000): usually crescentic, usually due to venous bleeding. May cover larger surface area than EDH (dural adherence to inner table limits extension of EDH). Chronology of SDH: acute = high density, subacute ≈ isodense, chronic ≈ low density
   b) subarachnoid blood: trauma is the most common cause of subarachnoid hemorrhage (SAH). Unlike aneurysmal SAH (aSAH) (p. 1453) where blood is typically thickest near the circle of Willis, traumatic SAH (tSAH) usually appears as high density spread thinly over the convexity, filling sulci (▶ Fig. 60.2) or basal cisterns. However, when the history of trauma is not clear, a CTA (or catheter arteriogram) may be indicated to R/O a ruptured aneurysm (that might have precipitated the trauma in some cases)
   c) intracerebral hemorrhage (ICH): increased density in brain parenchyma
   d) hemorrhagic contusion (p. 1071): often “fluffy” inhomogeneous high-density areas within brain parenchyma, usually adjacent to bony prominences (frontal and occipital poles, sphenoid wing). Typically less well-defined than primary ICH
   e) intraventricular hemorrhage (p. 1454): present in ≈ 10% of severe head injuries.[27] Associated with poor outcome; may be a marker for severe injury rather than the cause of the poor outcome. Use of intraventricular rt-PA has been reported for treatment[28]
2. hydrocephalus: enlarged ventricles may sometimes develop following trauma

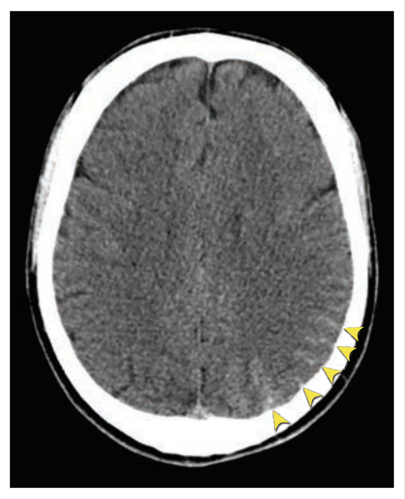


Fig. 60.2 Traumatic subarachnoid hemorrhage (tSAH) in a 22-year-old patient following an assault, demonstrating an example of tSAH (*yellow arrowheads*) overlying the high left convexity.
Image: noncontrast axial CT, brain windows.

3. cerebral swelling: obliteration of basal cisterns (p. 1109), compression of ventricles and sulci…
4. evidence of cerebral anoxia: loss of gray-white interface, signs of swelling
5. skull fractures (best appreciated using bone windows):
   a) basal skull fractures (including temporal bone fracture)
   b) orbital blow-out fracture
   c) calvarial fracture (CT may miss some linear nondisplaced skull fractures especially if the fracture is in the same plane as the CT slice)
      - linear vs. stellate
      - open vs. closed
      - diastatic (separation of sutures)
      - depressed vs. nondepressed: CT helps assess need for surgery
6. ischemic infarction (stroke): findings are usually minimal or subtle if < 24 hrs since stroke (DWI MRI is the test of choice for this)
7. pneumocephalus: may indicate skull fracture (basal or open convexity)
8. shift of midline structures (due to extra- or intra-axial hematomas or asymmetric cerebral edema): midline shift (p. 1110) can be associated with altered levels of consciousness

► **Marshall CT classification of TBI.** The Marshall CT classification (► Table 60.6 [29] has 6 categories of TBI severity based on the presence or absence of the factors shown below on a non-contrast head CT. The Marshall score was devised for descriptive purposes, the "Rotterdam score" ► Table 60.7 [30] is a stronger predictor of outcome.

1. intracranial abnormalities
2. CT evidence of increased ICP as demonstrated by
   a) midline shif (MLS) > 5 mm and/or
   b) compression of basal cisterns
3. presence or absence of mass lesions (contusions/hemorrhages)
4. planned evacuation of mass lesions

► **Rotterdam score for TBI.** The Marshall score was devised for descriptive purposes, and while it was subsequently shown to correlate with outcome parameters, including mortality, outcome prediction is stronger with the specific CT findings identified by recursive partitioning analysis in the "Rotterdam score" (► Table 60.7) which is calculated from a non-contrast head CT obtained within 4 hours of injury. There is evidence that the *worst* CT scan obtained during the admission has greater predictive value.[31]

The points from ► Table 60.7 are summed, and the predicted 6-month mortality is shown in ► Table 60.8.

Table 60.6 Marshall CT classification of TBI severity[29]

Category	Description	Mortality[30]
I - diffuse injury	• no visible pathology	6.4%
II - diffuse injury	• MLS[a] = 0 to 5 mm • basal cisterns remain visible • no high or mixed density lesions ≥ 25 cm^3 estimated volume[b], may include bone fragments & foreign bodies	11%
III - diffuse injury (swelling)	• MLS = 0 to 5 mm • basal cisterns compressed or completely effaced[c] • no high or mixed density lesions ≥ 25 cm^3	29%
IV - diffuse injury (shift)	• MLS > 5 mm • no high or mixed density lesions ≥ 25 cm^3	44%
V - evacuated mass lesion	• any lesion evacuated surgically	30%
VI - non-evacuated mass lesion	• high or mixed density lesions ≥ 25 cm^3 • not surgically evacuated	34%

[a] "MLS" = midline shift (p. 1110)
[b] to estimate volume of mass on CT (p. 1616)
[c] to assess the basal cisterns (p. 1109)

Table 60.7 "Rotterdam score" for CT findings in TBI

Feature		Points	Score
basal cisterns (p. 1109)	normal	0	**(0 - 2)**
	compressed	1	
	absent	2	
midline shift (MLS) (p. 1110)	0–5 mm	0	**(0 - 1)**
	> 5 mm	1	
epidural mass lesion	absent	0	**(0 - 1)**
	present	1	
intraventricular blood or traumatic SAH (tSAH)	absent	0	**(0 - 1)**
	present	1	
add 1 point[a]			**+ 1**
Rotterdam score → TOTAL			**(1 - 6)**

[a] one point is added to all scores to bring the range from 1 to 6 in a nod to the original Marshall score

Table 60.8 Mortality associated with total "Rotterdam scores"[a]

Score	Mortality number & %
1	0/36 (0%)
2	41/600 (6.8%)
3	122/773 (16%)
4	121/465 (26%)
5	138/261 (53%)
6	69/114 (61%)

[a] 6-month mortality

60.5.4 Follow-up CT

Routine follow-up CT (when there is no indication for urgent follow-up CT, see below):

1. it is our practice to perform a “stability scan” (a repeat head CT) with ≈ 24 hours (usually about 6-12 hours) for patients who are clinically stable but had findings on initial head CT of: traumatic SAH, small SDH or EDH, intraparenchymal contusions
2. for patients with *severe* head injuries:
   a) for *stable* patients, follow-up CTs are usually obtained between day 3 to 5 (some recommend at 24 hrs also) and again between day 10 to 14
   b) some recommend routine follow-up CT several hours after the “time zero” CT (i.e., initial CT done within hours of the trauma) to rule out delayed EDH (p. 1075), SDH (p. 1081), or traumatic contusions (p. 1071) [32]
3. for patients with mild to moderate head injuries:
   a) for those with an abnormal initial CT, the CT scan is usually repeated prior to discharge
   b) stable patients with mild head injury and normal initial CT do not require follow-up CT

Urgent follow-up CT: performed for neurological deterioration (loss of ≥ 2 points on the GCS, development of hemiparesis or new pupillary asymmetry), persistent vomiting, worsening H/A, seizures or unexplained rise in intracranial pressure **(ICP)** in patients with an ICP monitor.

60.5.5 Spine films

1. cervical spine: must be cleared radiographically from the cranio-cervical junction down through and including the C7–1 junction. Spinal injury precautions (cervical collar…) are continued until the C-spine is cleared. The steps in obtaining adequate films are outlined in *Spine injuries*, Radiographic evaluation and initial C-spine immobilization (p. 1141)
2. thoracic and lumbosacral LS-spine films should be obtained based on physical findings and on mechanism of injury (rarely for isolated TBI, especially in a patient who can tell you if they have spine tenderness on palpation); see *Spine injuries*, Radiographic evaluation and initial C-spine immobilization (p. 1141)

60.5.6 Skull X-rays

Practice guideline: Skull X-rays (SXR) in evaluating mTBI

Level II[20]: skull X-rays (SXR) are not recommended for evaluating mTBI

A skull fracture increases the probability of a surgical intracranial injury (ICI) (in a comatose patient it is a 20-fold increase, in a conscious patient it is a 400-fold increase[33,34]). However, significant ICI can occur with a normal skull X-ray (SXR) (SXR was normal in 75% of minor head injury patients found to have intracranial lesions on CT, attesting to the insensitivity of SXRs[35]). SXRs affect management of only 0.4–2% of patients in most reports.[36]

A skull X-ray (SXR) may be helpful in the following:

1. if a CT scan cannot be obtained, an SXR may identify significant findings such as pineal shift, pneumocephalus, air-fluid levels in the air sinuses, skull fracture (depressed or linear)… (however, sensitivity for detecting ICI is very low)
2. with penetrating injuries: helps by visualization of radio-opaque objects

60.5.7 MRI scans in trauma

Usually not appropriate for acute head injuries. This is due to longer acquisition time, less access to patients during study, increased difficulty in supporting patients (requires special non-magnetic ventilators, cannot use most IV pumps…), and MRI is less sensitive than CT for detecting acute blood.[37] There were no *surgical* lesions demonstrated on MRI that were not evident on CT in one study.[38] There may be some additional benefit in combining CT with an MRI performed directly in the emergency department.[39]

MRI may be helpful later after the patient is stabilized, e.g., to evaluate brainstem injuries, small white matter changes,[40] e.g., punctate hemorrhages in the corpus callosum seen in diffuse axonal injury (p. 1026)… Spinal MRI is indicated in patients with spinal cord injuries.

Rapid sequence MRI may be useful for follow-up in pediatrics to minimize radiation exposure.

60.5.8 Arteriogram in trauma

Cerebral arteriogram (p. 1096): useful with non missile penetrating trauma.

60.6 E/R management for minor or moderate head injury

60.6.1 Indications for admission to the hospital vs. observation at home

▶ **Patients who may be discharged with observation at home.** Patients with mild TBI (GCS = 14-15) who meet criteria in ▶ Table 60.9 may be managed with observation at home with written head-injury discharge instructions, e.g., as illustrated in ▶ Table 60.10.

For those not meeting discharge criteria, see sample admitting orders (p. 1012).

Table 60.9 Criteria for observation at home

1. head CT scan not indicated (see indications (p. 1006)), or CT scan normal if indicated[41]
2. initial GCS ≥ 14
3. patient is now neurologically intact (amnesia for the event is acceptable)
4. there is a responsible, sober adult that can observe the patient
5. patient has reasonable access to return to the hospital E/R if needed
6. no “complicating” circumstances (e.g., no suspicion of domestic violence, including child abuse)

Table 60.10 Sample discharge home instructions for head injuries

Seek medical attention for any of the following:

1. a change in level of consciousness (including difficulty in awakening)
2. abnormal behavior
3. increased headache
4. slurred speech
5. weakness or loss of feeling in an arm or leg
6. persistent vomiting
7. enlargement of one or both pupils (the black round part in the middle of the eye) that does not get smaller when a bright light is shined on it
8. seizures (also known as convulsions or fits)
9. significant increase in swelling at injury site

Do not take sedatives or pain medication stronger than acetaminophen (paracetamol in some countries) for 48 hours. Do not take aspirin or other anti-inflammatory medications because of interference with platelet function and theoretical increased risk of bleeding

60.6.2 Admitting orders for minor head injury (GCS ≥ 14)

1. activity: BR with HOB elevated 30–45°
2. neuro checks q 2 hrs (q 1 hr if more concerned; consider ICU for these patients). Contact physician for neurologic deterioration
3. NPO until alert; then clear liquids, advance as tolerated
4. isotonic IVF (e.g., NS + 20 mEq KCl/L) run at maintenance (p. 1050): ≈ 100 cc/hr for average size adult (peds: 2000 cc/m^2/d). **Note:** the concept of “running the patient dry” is obsolete
5. mild analgesics: acetaminophen (PO, or PR if NPO), codeine or tramadol if necessary
6. anti-emetic: give infrequently to avoid excessive sedation, avoid phenothiazine anti-emetics (which lower the seizure threshold); e.g., use trimethobenzamide (Tigan®) 200 mg IM q 8 hrs PRN for adults

60.6.3 Admitting orders for moderate head injury (GCS 9–13)

1. orders as for minor head injury (see above) except patient is kept NPO in case surgical intervention is needed (including ICP monitor)
2. for GCS = 9–12 admit to ICU. For GCS = 13, admit to ICU if CT shows any significant abnormality (hemorrhagic contusions unless very small, rim subdural…)
3. patients with normal or near-normal CTs should improve within hours. Any patient who fails to reach a GCS of 14–15 within 12 hrs should have a repeat CT at that time[42]

60.7 Patients with associated severe systemic injuries

60.7.1 Intra-abdominal injuries

Diagnostic peritoneal lavage (DPL) looking for bloody fluid or FAST (focused abdominal sonogram for trauma) are often used by trauma surgeons to assess for intra-abdominal hemorrhage. If negative and the patient is hemodynamically stable, the patient should be taken for cranial CT (with DPL—if the initial fluid is not bloody, the remainder of the lavage fluid may be collected for quantitative analysis as the head CT is being done).

Patients with grossly positive DPL or positive FAST and/or hemodynamic instability may need to be rushed to the O.R. for emergent laparotomy by trauma surgeons without benefit of cerebral CT. Neurosurgical management is difficult in these patients, and must be individualized. These guidelines are offered:

✖ CAUTION: many patients with severe trauma may be in DIC (either due to systemic injuries, or directly related to severe head injury possibly because the brain is rich in thromboplastin[43]). Operating on patients in DIC is usually disastrous (p. 175). At the least, check a PT/INR/PTT

1. if GCS > 8 (which implies at least localizing)
   a) operative neurosurgical intervention is probably not required
   b) utilize good neuroanesthesia techniques (elevate head of bed, judicious administration of IV fluids, avoiding prophylactic hyperventilation…)
   c) obtain a head CT scan immediately post-op
2. if patient has focal neurologic deficit, an exploratory burr hole should be placed in the O.R. simultaneously with the treatment of other injuries. Placement is guided by the pre-op deficit (p. 1014)
3. if there is severe head injury (GCS ≤ 8) without localizing signs, or if initial burr hole is negative, or if there is no pre-op neuro exam, then
   a) measure the ICP: insert a ventriculostomy catheter (if the lateral ventricle cannot be entered after 3 passes, it may be completely compressed or it may be displaced, and an intraparenchymal fiberoptic monitor or subarachnoid bolt should be used)
      - normal ICP: unlikely that a surgical lesion exists. Manage ICP medically and, if an IVC was inserted, with CSF drainage
      - elevated ICP (≥ 2 mm Hg): inject 3–4 cc of air into ventricles through IVC, then obtain portable intraoperative AP skull X-ray (intraoperative pneumoencephalogram) to determine if there is any midline shift. If there is mass effect with ≥ 5 mm of midline shift, explore surgically[44] with burr hole(s) on the side opposite the direction of shift. If no mass effect, intracranial hypertension is managed medically and with CSF drainage
   b) routine use of exploratory burr holes for children with GCS = 3 has been found not to be justified[45]

60.7.2 Fat embolism syndrome

General information

Most often seen after a long bone fracture (usually femoral, but may include clavicular, tibial, and even isolated skull fracture). Although almost all patients have pulmonary fat emboli at autopsy, the syndrome is usually mild or subclinical, only ≈ 10–20% of cases are severe, and the fulminant form leading to multiple organ failure is rare. Clinical findings usually appear within 12–72 hrs of injury, and do not always include the complete classic clinical triad of:

- acute respiratory failure (including hypoxemia, tachypnea, dyspnea) with diffuse pulmonary infiltrates (usually seen as bilateral fluffy infiltrates). May be the only manifestation of fat emboli in up to 75% of cases
- global neurologic dysfunction: may include confusion (PaO_2 usually not low enough to account for these changes[46]), lethargy, seizures
- petechial rash: seen ≈ 24–72 hrs after the fracture, usually over thorax

Other possible findings include:

- pyrexia
- retinal fat emboli

There is no specific test for fat embolism syndrome (FES). The following have been proposed, but have poor sensitivity and specificity: fat globules in the urine (positive in ≈ one–third[47]) and serum, serum lipase activity. In cases of unexplained neurologic or pulmonary abnormalities, it may be possible to diagnose FES if on bronchoalveolar lavage[48] > 5% of cells in the washings staining for neutral fat with red oil 0. Nonspecific tests include ABG (findings: hypoxemia, hypocarbia from hyperventilation, respiratory alkalosis).

Treatment

Pulmonary support with oxygen, and mechanical ventilation if necessary including use of PEEP. The use of steroids is controversial. Ethyl alcohol (to decrease serum lipase activity) and heparin have not been shown to be of benefit. Early operative fixation of long bone fractures may reduce the incidence of FES.[49]

Outcome

Usually related more to the underlying injuries. Although FES itself is usually compatible with good recovery, 10% mortality is usually quoted.

60.7.3 Indirect optic nerve injury

General information

≈ 5% of head trauma patients manifest an associated injury to some portion of the visual system. Approximately 0.5–1.5% of head trauma patients will sustain indirect injury (as opposed to penetrating trauma) to the optic nerve, most often from an ipsilateral blow to the head (usually frontal, occasionally temporal, rarely occipital).[19] The optic nerve may be divided into 4 segments: intraocular (1 mm in length), intraorbital (25–30 mm), intracanalicular (10 mm), and intracranial (10 mm). The intracanalicular segment is the most common one damaged with closed head injuries. Funduscopic abnormalities visible on initial exam indicates anterior injuries (injury to the intraocular segment (optic disc) or the 10–15 mm of the intraorbital segment immediately behind the globe where the central retinal artery is contained within the optic nerve), whereas posterior injuries (occurring posterior to this but anterior to the chiasm) take 4–8 weeks to show signs of disc pallor and loss of the retinal nerve fiber layer.

Treatment

See reference.[19]

No prospective study has been carried out. Optic nerve decompression has been advocated for indirect optic nerve injury; however, the results are not clearly better than expectant management with the exception that documented *delayed* visual loss appears to be a strong indication for surgery. Transethmoidal is the accepted route, and is usually done within 1–3 weeks from the trauma.[50] The use of "megadose steroids" may be appropriate as an adjunct to diagnosis and treatment.

60.7.4 Posttraumatic hypopituitarism

Trauma is a rare cause of hypopituitarism. It may follow closed head injury (with or without basilar skull fracture) or penetrating trauma.[51] In 20 cases in the literature[52] all had deficient growth hormone and gonadotropin, 95% had corticotropin deficiency, 85% had reduced TSH, 63% had elevated PRL. Only 40% had transient or permanent DI.

60.8 Exploratory burr holes

60.8.1 General information

In a trauma patient, the clinical triad of altered mental status, unilateral pupillary dilatation with loss of light reflex, and contralateral hemiparesis is most often due to upper brainstem compression by uncal transtentorial herniation which, in the majority of trauma cases, is due to an extraaxial intracranial hematoma. Furthermore, the prognosis of patients with traumatic herniation is poor. Outcome may possibly be improved slightly by increasing the rapidity with which decompression is undertaken; however, an upper limit of salvageability is probably still only ≈ 20% satisfactory outcome.

Burr holes are primarily a *diagnostic tool*, as bleeding cannot be controlled and most acute hematomas are too congealed to be removed through a burr hole. However, if the burr hole is positive, it is possible that modest decompression may be performed, and then the definitive craniotomy can be undertaken incorporating the burr hole(s).

With widespread availability of quickly accessible CT scanning, exploratory burr holes are infrequently indicated.

60.8.2 Indications

1. clinical criteria: based on deteriorating neurologic exam. Indications in E/R (rare): patient dying of rapid transtentorial herniation (see below) or brainstem compression that does not improve or stabilize with mannitol and hyperventilation.[53]
   a) indicators of transtentorial herniation/brainstem compression:
      - sudden drop in Glasgow Coma Scale (GCS) score
      - one pupil fixes and dilates
      - paralysis or decerebration develops (usually contralateral to blown pupil)
   b) recommended situations where criteria should be applied:
      - neurologically stable patient undergoes *witnessed* deterioration as described above
      - awake patient undergoes same process in transport, and changes are well documented by competent medical or paramedical personnel
2. other criteria
   a) some patients needing emergent surgery for systemic injuries (e.g., positive peritoneal lavage + hemodynamic instability) where there is not time for a brain CT (p. 1013)

60.8.3 Management

Controversial. The following should serve only as guidelines:

1. if patient fits the above criteria (emergent operation for systemic injuries or deterioration with failure to improve with mannitol and hyperventilation), and CT scan cannot be performed and interpreted immediately, then treatment should not wait for CT scan
   a) in general, if the O.R. can be immediately available, burr holes are preferably done there (equipped to handle craniotomy, better lighting and sterility, dedicated scrub nurse…), especially in older patients (> 30 yrs) not involved in MVAs (see below). This may more rapidly diagnose and treat extraaxial hematomas in herniating patients, although no difference in outcome has been proven
   b) if delay in getting to the O.R. is foreseen, emergency burr holes in the E/R should be performed
2. placement of burr hole(s) as outlined under Technique below

60.8.4 Technique

Position

Shoulder roll, head turned with side to be explored up. Three pin skull-fixation used if concern about possible aneurysm or AVM (to allow for retractors and increased stability) or if additional stability is desired (e.g., with unstable cervical fractures); otherwise a horse-shoe head-holder suffices and saves time and makes it easier to turn the head to access to the other side if needed.

Choice of side for initial burr hole

Start with a temporal burr hole (see below) on the side:

1. ipsilateral to a blown pupil. This will be on the correct side in > 85% of epidurals[54] and other extra-axial mass lesions[55]
2. if both pupils are dilated, use the side of the *first* dilating pupil (if known)
3. if pupils are equal, or it is not known which side dilated first, place on side of obvious external trauma
4. if no localizing clues, place hole on *left* side (to evaluate and decompress the dominant hemisphere)

Approach

Burr holes are placed along a path that can be connected to form a “trauma flap” if a craniotomy becomes necessary (▶ Fig. 60.3). The “trauma flap” is so-called because it provides wide access to most of the cerebral convexity permitting complete evacuation of acute blood clot and control of most bleeding.

First outline the trauma flap with a skin marker:

1. start at the zygomatic arch < 1 cm anterior to the tragus (spares the branch of the facial nerve to the frontalis muscle and spares the anterior branch of the superficial temporal artery (STA))
2. proceed superiorly and then curve posteriorly at the level of top of the pinna
3. 4–6 cm behind the pinna it is taken superiorly
4. 1–2 cm ipsilateral to the midline (sagittal suture) curve anteriorly to end behind the hairline

Burr hole locations

- temporal burr hole (1 in ► Fig. 60.3)
  - over middle cranial fossa typically on side of dilated pupil (if there is one) just superior to the zygomatic arch. Provides access to middle fossa (the most common site of epidural hematoma) and usually allows access to most convexity subdural hematomas, as well as proximity to middle meningeal artery in region of pterion
  - if no epidural hematoma, the dura is opened if it has bluish discoloration (suggests subdural hematoma (SDH)) or if there is a strong suspicion of a mass lesion on that side
- if completely negative, usually perform temporal burr hole on contralateral side in the same location (not shown)
- if negative and if a CT cannot now be done and the OR immediately available from there, proceed to
  - ipsilateral frontal burr hole (2 in ► Fig. 60.3), if negative proceed to
  - parietal region (3 in ► Fig. 60.3), if negative proceed to
  - posterior fossa (4 in ► Fig. 60.3)

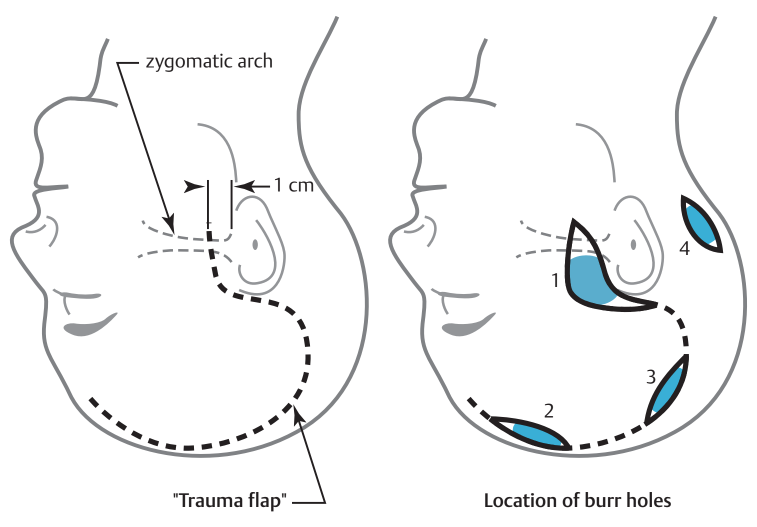

Fig. 60.3 Exploratory burr hole placement illustrating the technique to place the burr holes (blue circles) along an imaginary skin incision (broken line) that could be converted to a "trauma flap" - excluding burr hole 4 (adapted[55,56]).

Literature

In 100 trauma patients undergoing transtentorial herniation or brainstem compression as outlined above,[55] exploratory burr holes (bilateral temporal, frontal, and parietal, done in the O.R.) were positive in 56%. Lower rates in younger patients (< 30 yrs) and those in MVAs (as opposed to falls or assaults). SDH was the most common extraaxial mass lesion (alone and unilateral in 70%, bilateral in 11%, and in combination with EDH or ICH in > 9%).

When burr holes were positive, the first burr hole was on the correct side 86% of the time when placed as suggested above. Six patients had significant extraaxial hematomas missed with exploratory burr holes (mostly due to incomplete burr hole exploration). Only 3 patients had the above neurologic findings as a result of intraparenchymal hematomas.

Outcome

Mean follow-up: 11 mos (range: 1–37). 70 of the 100 patients died. No morbidity or mortality was directly attributable to the burr holes. Four patients with good outcome and 4 with moderate disability had positive burr holes.

61 Concussion, High-Altitude Cerebral Edema, Cerebrovascular Injuries

61.1 Concussion

61.1.1 General information

Key concepts

- a traumatic biomechanically induced complex pathophysiologic process affecting the brain with no identifiable structural abnormalities on imaging studies
- concussion is a subset of mild TBI (mTBI) and is therefore not equivalent to mTBI
- indicators of concussion: posttraumatic alterations in any of: orientation, balance, speed of reaction, and/or impaired verbal learning and memory in a patient with GCS 13–15[1]
- does not require loss of consciousness (LOC) or even a direct blow to the head
- grading scales have been abandoned in favor of experienced assessment assisted by various "sideline" tools, ideally with baseline (pre-injury) metrics for comparison

Concussion occurs in a subset of patient with mild traumatic brain injury (mTBI; ► Fig. 60.1). It is considered "mild" because it is usually not life-threatening by itself. While most victims recover completely, effects of concussion can be serious, and in some instances, may be lifelong.

Much of the discussion in this chapter relates to concussion in sports, which is the largest source of data on the subject, and generalization to other types of trauma must be done circumspectly.

There has been a move away from concussion grading scales. The current recommendation is for the diagnosis to be determined by an experienced examiner with the assistance of various assessment tools, ideally with the availability of pre-injury baseline metrics for comparison.

Concussion can occur without a direct blow to the head, e.g., with violent shaking of the torso and head. Concussion symptoms can present soon after an insult or in a delayed fashion.

The subject may not be aware that they have sustained a concussion.

61.1.2 Epidemiology

Incidence: 1.6–3.8 million concussions occur per year in the United States from sports and recreational activities. It is estimated that 50% of concussions go unreported.[2]

61.1.3 Concussion genetics

There is no clear evidence to support a genetic predisposition to concussion. Apolipoprotein E4, Apo E G-219 T promoter and tau exon 6 have been studied in small retrospective and prospective trials without definitive association.[2,3]

61.1.4 Concussion—definition

There is no universally accepted definition for concussion.[4] Of the many contemporary definitions,[2,3,4,5,6,7] most key elements are contained in the Concussion in Sport Group 2012 consensus definition[3] summarized below. However, opinions differ e.g., whether there is any long-term effect of concussion or if that necessitates a different diagnosis.

► **Definition.** Concussion is a complex pathophysiological process affecting the brain resulting in alteration of brain function, that is induced by nonpenetrating biomechanical forces, without identifiable abnormality in standard structural imaging.

The Concussion in Sport Group[3] elaborates on this definition as follows:

- results in a graded set of neurological symptoms that may or may not involve loss of consciousness (LOC)
- symptom onset is usually rapid, short-lived and resolves spontaneously. Manifestations may include transient deficits in balance, coordination, memory/cognition, strength, or alertness

- may result in neuropathological changes, but the acute clinical symptoms largely reflect a functional disturbance rather than a structural injury
- resolution of the clinical and cognitive features typically follows a sequential course

61.1.5 Concussion versus mTBI

- concussion and mTBI are not interchangeable. Concussion may be thought as a subcategory of mTBI on the less severe end of the brain injury spectrum, though with similar clinical symptoms[2,5,6,8] (see ▶ Fig. 60.1)
- a major difference between the two is that mTBI may demonstrate abnormal structural imaging (such as cerebral hemorrhage/contusion) and concussion, by definition, must have normal imaging studies. mTBI is part of an injury severity spectrum primarily based on GCS score. TBI is evaluated 6 hours after injury and differentiated into mild, moderate and severe; see Grading (p. 1000). Concussion is evaluated directly after the insult and based on a clinical diagnosis aided by a multitude of standardized assessment tools. To include concussion under the full spectrum of traumatic brain injury then it must fall at the low end of mTBI and overlap with the subset of "minimal" injury. Most mTBIs with negative imaging can be considered concussions, but the majority of sports concussions cannot be classified as mTBI[5,8]

61.1.6 Risk factors for concussion

- history of previous concussion increases risk for further concussion
- being involved in an accident: bicyclist, pedestrian or motor vehicle collision
- combat soldier
- victim of physical abuse
- falling (especially pediatrics or elderly)
- males are diagnosed with sports-related concussion more than females (due to increased number of male participation in sports studied) but females have a higher risk overall when compared to males who play in the same sport (i.e., soccer and basketball)[7]
- articipating in sports with high risk of concussion:
  - American football
  - Australian rugby
  - ice hockey
  - boxing
  - ★ soccer is the highest risk for females
- (for contrast, sports with the lowest risk of concussion: baseball, softball, volleyball & gymnastics)
- BMI > 27 kg/m^2 and less than 3 hours of training per week increases the risk of sports-related concussion[7]

61.1.7 Diagnosis

Triggers

Findings suggestive of concussion are listed in ▶ Table 61.1. The diagnosis of concussion should be considered when any of these findings occur following trauma. In pre-verbal children, findings may include those in ▶ Table 61.2.

General diagnostic information

Clinical evaluation

No physiologic measure has been identified that can detect the underlying changes that lead to the manifestations of concussion. Therefore the diagnosis relies on: self-reporting of abnormal function (symptoms), observed physiologic abnormalities (signs) including assessment of cognitive dysfunction,[11] sometimes with the assistance of imaging tests to rule out a structural substrate.

A clinical diagnosis of concussion is made if there are abnormal findings in balance, coordination, memory/cognition, strength, reaction speed, or alertness after a traumatic insult to the head. Findings include confusion, amnesia, headache, drowsiness or LOC (LOC is *not* a requirement for diagnosing concussion,[6] patients themselves may be unaware whether or not they experienced LOC[4]). Frequent neurobehavioral features of concussion are shown in ▶ Table 61.1. In children who may not be able to verbalize their symptoms, evidence of concussion may include findings in ▶ Table 61.2. Positive imaging findings would necessitate a more severe diagnosis such as cerebral contusion.

Table 61.1 Possible findings in concussion[2,9,10]

Physical	Cognitive	Emotional	Sleep
• vacant stare or befuddled expression • dazed or stunned • headache or pressure sensation in the head • nausea • vomiting • fatigue • "seeing stars" • photophobia • phonophobia • ringing in the ears (tinnitus) • delayed verbal & motor responses: • difficulty focusing attention • inability to perform normal activities • speech alterations: slurred or incoherent, disjointed or incomprehensible statements • incoordination stumbling • any period of LOC, paralytic coma, unresponsiveness to stimuli	• feeling like being in a fog • slow to answer questions or follow instructions • easy distractibility • disorientation (e.g., walking in the wrong direction) • unaware of date, time or place • memory deficits: amnesia for the event • repeatedly asking same question that has been answered	• exaggerated emotionality: inappropriate crying • distraught appearance • irritability • nervousness	• drowsiness • insomnia • hypersomnia • difficulty falling asleep or staying asleep

Table 61.2 Concussion findings in children

listlessness and easy fatigability, change in sleeping patterns
irritability
appearing dazed
balance impairment
excessive crying
change in eating habits
loss of interest in favorite toys

Approach

- take a concussion specific symptom survey including inquiries about: H/A, N/V, light sensitivity, tinnitus, feeling like being in a fog, sleep disturbances
- history of diagnoses that might have an impact on the assessment or on a current concussion
  - history of prior concussions
  - H/A history
  - ADD/HD
  - learning disabilities
  - medications (prescribed and other) that might affect alertness or cognition
- perform a good general neurological exam
- include a concussion specific neuro exam
  - check orientation
  - assess for amnesia and impaired verbal memory
  - balance: Romberg test (look for significant sway or breaking stance), single leg stance
  - eye movements: optokinetic nystagmus (OKN), smooth pursuit
  - simultaneous task performance: e.g., snap fingers while walking
- include assessment aides ("sideline tools") as appropriate (see below)

Assessment aids

- there is no single validated assessment tool to diagnose concussion.[4] It is primarily a *clinical* diagnosis that is ideally made by certified healthcare providers who are familiar with the patient based on a detailed history and physical examination and a continuum of evaluation from the sideline to the clinic (diagnosis is ideally made within 24 hours of injury)[2,3,4,5,6,7]

- diagnosis may be aided by concussion assessment tools such as the SCAT3, ImPACT™.
✖ No test has shown high validity on independent testing, and no test should be used as the sole method of diagnosing concussion or for determining suitability for return to play. Athletes have also learned to "game" some baseline tests to avoid removal from play after possible concussion
- SCAT3 (Sports Concussion Assessment Tool – 3rd Edition)[12]: Derived from the 2012 Zurich Conference.[3] The SCAT has become the most commonly used standardized tool for sideline assessment of sport concussion. The sensitivity and specificity of concussion assessment tools change over the course of a concussion so a tool designed for sideline use (i.e., SCAT3) is not appropriate for office use
    - SCAT3™ is a trademarked tool developed by the Concussion in Sports Group for use only by medical professionals for assessing sports-related concussion
    - it can be found at http://bjsm.bmj.com/content/47/5/259.full.pdf
    - to be used in athletes of 13 years or older (for 12 and younger, use Child SCAT3[13])
    - is a multimodal assessment tool with 8 sections that includes self-reported symptoms and evaluation of functional domains such as cognition, memory, balance, gait and motor skills
    - takes 8–10 min to administer
    - a "normal" SCAT3 does *not* rule out concussion
    - it has not been validated
- other types of sports concussion assessment tools (many can be viewed on YouTube):
    - neurocognitive testing (may take up to 20 minutes to administer)
    - SAC (Standardized Assessment of Concussion)[14]: a neurocognitive test that includes tests of immediate memory, delayed recall, serial 7's, digit span
    - ImPACT™ (Immediate Post-Concussion Assessment and Cognitive Testing): a widely used commercially produced computer test (https://www.impacttest.com). Independent validation studies have yielded conflicting results and results can diverge from observations[15]
    - PCSS (Post-Concussive Symptom Scale)
    - CSI (Concussion Symptom Inventory)
    - BESS (Balance Error Scoring System): the subject stands in each of various standardized positions for 20 seconds each, and the number of errors are recorded (breaking stance, opening eyes, taking hands off hip…).
    - SOT (Sensory Organization Test)
    - "Concussion Quick Check" app for mobile devices produced by the AAN
    - King-Devick eye movement testing: only takes 2–3 minutes to administer. On printed cards or tablet computer (http://kingdevicktest.com/for-concussions/)
- formal neuropsychological testing: it is recommended that this be reserved for patients with prolonged cognitive symptoms
- concussion serum biomarkers: no moiety has been identified that can reliably diagnose concussion on serum or saliva testing. Neuron-specific enolase, S100, and cleaved tau protein have been studied for prognostication after mTBI and concussion. S100 has demonstrated only a 33.3% sensitivity for postconcussive symptoms and 93% sensitivity for an Extended Glasgow Outcome Scale (▶ Table 98.4) score < 5 at 1 month. Another study involving pediatric patients with mTBI showed no difference in levels of neuron-specific enolase or S100B in asymptomatic and symptomatic children. A prospective study found no significant correlation between cleaved tau protein and postconcussive syndrome in patients with mTBI[16]

On-site/sideline evaluation

Any individual suspected of having a concussion (displaying ANY findings in ▶ Table 61.1) should be removed from the activity (for athletes, stopped from playing) and assessed by a licensed healthcare provider trained in the evaluation and management of concussions with attention to excluding a cervical spine injury.[2,3] If no provider is available, return to the activity is not permitted and urgent referral to a physician should be arranged.

After ruling out emergency issues, the provider should perform a concussion assessment (may employ standardized tools such as SCAT3™ or other methodologies).

The patient should not be left alone, and serial evaluations for signs of deterioration should be made over the following few hours.

For return to play guidelines, see below.

61.1.8 Indications for imaging or other diagnostic testing in concussion

There is no imaging modality that is diagnostic for concussion. Imaging in concussion is typically used to rule out more serious traumatic injuries, or sometimes to "clear" a patient of occult intracranial pathology before general anesthesia for other injuries. Typically CT, or sometimes MRI, is utilized.

► **CT scan (or sometimes MRI) in concussion.** CT scans should not be performed routinely for mTBI. Validated decision rules (p. 1019) should be employed to determine when imaging is indicated.

► **Other studies (imaging and electrodiagnostic)**

- diffusion tensor imaging (DTI) MRI: used to quantify white matter tract integrity throughout the brain with 4 types of analysis methods—voxel analysis, region of interest (ROI) analysis, histogram analysis, and tractography. There is no strong consensus regarding the best method for utilizing DTI for diagnosis or prognosis in the *individual* patient but multiple studies have shown *group* differences in DTI parameters between mTBI and control patients[8]
- functional MRI (fMRI): consists of 2 types (task-based fMRI and resting state fMRI) and is based on the blood oxygen level dependent (BOLD) effect, in which specialized MRI sequences measure/detect regions of increased oxygen rich blood flow to areas of upregulated neuronal activity. Both task-based and resting state fMRI modalities have shown *group* differences between mTBI and control patients (specifically in frontal lobe dysfunction), but further studies need to be completed on both a single time point and longitudinal basis before these techniques can be widely adopted for individual diagnosis and therapeutic guidance[8]
- imaging studies that are currently used primarily in concussion research: positron emission tomography (PET), single photon emission CT (CT-SPECT), MR-spectroscopy (MRS)
- quantitative EEG (qEEG): digitized EEGs are analyzed for relative energy at different frequencies to assess brain activity, patterns of cortical activation and neuronal networks. Post-concussion studies are compared to baseline. Thus far, there are no qEEG features (or other EEG findings for that matter) that are specific and sensitive for concussed patients[17]

61.1.9 Acute pathophysiology

Biomechanical force results in unregulated ionic flux (K^+ efflux, Na^+/Ca^{2+} influx) and unrestricted hyperacute glutamate release from sublethal mechanoporation of lipid membranes at the cellular level. This triggers voltage/ligand gated ion channels causing a cortical spreading depression-like state that is thought to be the substrate behind immediate postconcussive symptoms. Subsequently, ATP-dependent ionic pumps are extensively upregulated to restore cellular homeostasis causing widespread intracellular energy reserve depletion and an increase in ADP. Cells then pass into a state of impaired metabolism (energy crisis) that can last up to 7–10 days and may be associated with alterations in CBF. This impaired metabolic state is associated with vulnerability to repeat injury as well as behavioral and spatial learning impairments. Cells also undergo cytoskeletal damage, axonal dysfunction, and altered neurotransmission with the as yet unproven impression that each of these pathologic processes correlate with a separate symptomology (see ► Table 61.3).[18]

Table 61.3 Physiologic perturbations and their proposed corresponding symptomology[18]

Pertubation	Symptom
ionic influx →	migraine headache, photophobia, phonophobia
energy crisis →	vulnerability to second injury
axonal injury →	impaired cognition, slowed processing, slowed reaction time
impaired neurotransmission →	impaired cognition, slowed processing, slowed reaction time
protease activation, altered cytoskeletal proteins, cell death →	chronic atrophy, persistent impairments

61.1.10 Post concussion syndrome (PCS)

Occurs in 10%-15% of concussed individuals. As with most concussion related pathologies, there are multiple definitions of PCS. An amalgam of some definitions is as follows: Patients having ≥ 3 symptoms including headache, fatigue, dizziness, irritability, difficulty concentrating, memory difficulty, insomnia, and intolerance to stress, emotion, or alcohol, and symptoms must begin within 4 weeks of injury and remain for ≥ 1 month after onset of symptoms.[16,19] In one retrospective study, the following conclusions were reached[19]:

- > 80% of PCS patients had at least 1 previous concussion
- average number of previous concussions was 3.4

- median duration of PCS was 6 months
- 50% of patients were < 18 years of age
- LOC does not increase the risk for PCS

61.1.11 Prevention of concussion

- AAN guidelines conclude that protective headgear in rugby is “highly probable” to decrease the incidence of concussion.[7] However, the AMSSM (American Medical Society for Sports Medicine) hold that there is no clear evidence that soft or hard helmets reduce the severity or incidence of concussion (in football, lacrosse, hockey, soccer, and rugby).[2,3] Biomechanical studies have shown helmets reduced impact forces on the brain but this has not translated into concussion prevention.[3]
- there is insufficient data to determine whether one type of football helmet protects better than another in preventing concussions[3,7]
- no significant evidence that a mouthpiece protects against concussion[3,7]

61.1.12 Management of concussion and post-concussion syndrome

Return to Play (RTP)

- no system of return to play (RTP) guidelines has been rigorously tested and proven to be scientifically sound
- after sustaining a concussion, athletes should not return to play the same day.[2,3,4,5,6,7] Prohibited by some state laws
- ✖ a symptomatic player should not return to competition
- if there is any uncertainty: “When in doubt, sit them out”
- evaluation should proceed in a stepwise fashion. A player needs to be completely asymptomatic both at rest and with provocative exercise before full clearance is given.[3] There is no standardized RTP protocol. Each player’s progression should be individualized.[2] Generally, the athlete’s level of activity should be gradually increased over 24-hour increments from light aerobic activity to full contact practice. The athlete is evaluated after each progression. If postconcussive symptoms occur then the player is dropped back to the previous asymptomatic level and then allowed another attempt at progression after a 24-hour rest period. 80–90% of concussions resolve within 7–10 days. This recovery time may be longer for children or adolescents[3]
- the CDC endorses a graded 5-step return to play for student athletes[20] as shown in ▶ Table 61.4. The athlete should move to the next step only if they have no new symptoms. If symptoms return or new ones develop, then medical attention should be sought and after clearance the student can return to the previous step.

Contraindications for return to play are shown in ▶ Table 61.5.

Table 61.4 5-step return to play progression

Step	Description
Baseline	athlete is back to regular school activities without symptoms
1	light aerobic activity: only to increase heart rate for 5–10 minutes. No weight lifting
2	moderate activity: increase heart rate with body or head movement. May include moderate intensity weight training (less time and intensity than their typical routine)
3	heavy, non-contact activity: may include running, high-intensity stationary biking, regular weight training, non-contact sports-specific drills
4	practice & full contact: in controlled practice
5	competition

Table 61.5 Cerebral contraindications for return to contact sports

1. persistent postconcussion symptoms
2. permanent CNS sequelae from head injury (e.g., organic dementia, hemiplegia, homonymous hemianopsia)
3. hydrocephalus
4. spontaneous SAH from any cause
5. symptomatic (neurologic or pain producing) abnormalities about the foramen magnum (e.g., Chiari malformation)

Management of post-concussive syndrome

An extremely complicated topic, partly because of potential for litigation and the fact that symptoms are often vague and nonspecific and there may be no objective findings to corroborate subjective symptoms.

Most symptoms from concussion resolve within 7–10 days and do not require treatment. The most common exception to this is posttraumatic headache, the most common subtype being acute posttraumatic migraine.

Typical symptoms include: H/A, dizziness, insomnia, exercise intolerance, depression, irritability, anxiety, memory loss, difficulty concentrating, fatigue, light or noise hypersensitivity.

Patients with protracted symptoms may require more directed treatment.

- psychological and neuropsychological involvement is often employed
- pharmacologic treatment: there are no evidence-based studies of the utility of medications for post-concussive symptoms (aside from H/A)
- intractable headaches: occurs in ≈ 15% of concussions
  - expert neurology consultation is usually required for difficult-to-control headaches
  - the first line drugs are OTC medications
  - triptans are usually employed for nonresponders
  - third line drugs includ Ketorolac or DHE-45 (dihydroergotamine)
  - steroids may be beneficial for some
  - avoid: narcotics, butalbital/caffeine preparations (Fioricet, Esgic…), beta blockers, and calcium channel blockers

61.1.13 Second impact syndrome (SIS)

A rare condition described primarily in athletes who sustain a second head injury while still symptomatic from an earlier one. Classically, the athlete walks off the field under their own power after the second injury, only to deteriorate to coma within 1–5 minutes and then, due to vascular engorgement, develops malignant cerebral edema that is refractory to all treatment and progresses to herniation. Mortality: 50–100%.

A syndrome compatible with SIS was first described by Schneider[21] in 1973, and was later dubbed the “second impact syndrome of catastrophic head injury” in 1984.[22] Although it is contended that SIS is rare (if it exists at all) and may be overdiagnosed,[23] its apparent predilection for teens and children still warrants extra precaution following concussion.

61.1.14 Chronic traumatic encephalopathy (CTE)

There is limited evidence-based research involving the pathophysiology and natural history of CTE. Thought to be a distinct neurodegenerative disease (tauopathy) associated with repetitive brain trauma, not limited to athletes with reported concussions, and can only be diagnosed postmortem with a pathology-confirmed analysis. Small studies have shown that there is a variable age of onset with variable behavioral, mood, and cognitive deficits present at the time of death (92% symptomatic at time of death).[10,16]

See section about CTE (p. 1112) for further details.

61.2 Other TBI definitions and concepts

61.2.1 Contusion

A contusion is a TBI with CT findings that may include:

- high attenuation areas (AKA “hemorrhagic contusions” AKA traumatic intraparenchymal hemorrhages) (▶ Fig. 61.1): usually produce less mass effect than their apparent size. Most common in areas where sudden deceleration of the head causes the brain to impact on bony prominences (e.g., frontal and occipital bones, sphenoid wing, petrous bone). Contused areas may progress (or “blossom” in neuroradiological jargon) to frank parenchymal hematomas. Surgical decompression (p. 1071) may be considered if herniation threatens.
- low attenuation areas: representing associated edema

61.2.2 Contrecoup injury

In addition to the injury to the brain directly under the point of impact, the brain may rebound after the impact and be thrust against the skull at a point diagonally opposite the blow (▶ Fig. 61.1), the so-called contrecoup (French: “counter blow”) injury. This may produce contusions typically located subjacent to bony prominences listed above.

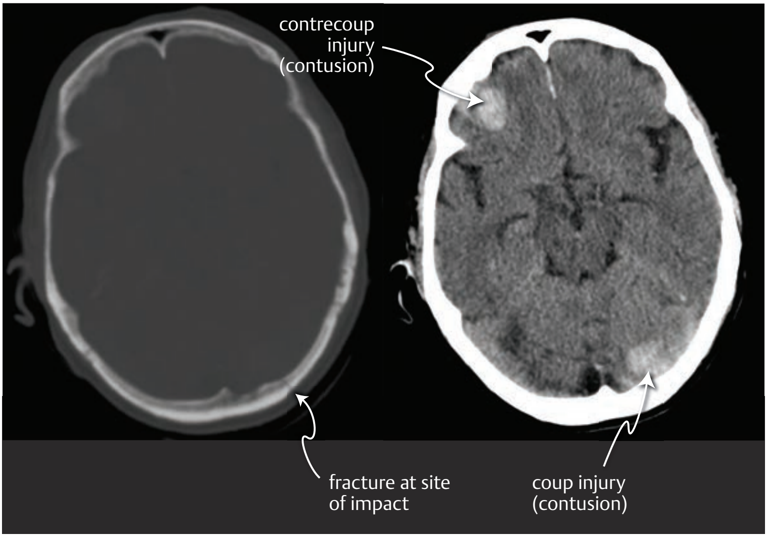

Fig. 61.1 Coup contrecoup injury in patient who fell, striking their occiput on the ground sustaining a skull fracture in the left occipital bone with a “coup injury” to the left cerebellum and a “contrecoup injury” to the right frontal lobe.
Image: axial CT scan of the brain, bone window on left, brain window on right.

61.2.3 Posttraumatic brain swelling

This term encompasses two distinct processes:

1. increased cerebral blood volume: may result from loss of cerebral vascular autoregulation. This hyperemia may sometimes occur with extreme rapidity, in which case it has sometimes been referred to as diffuse or “malignant cerebral edema,”[24] which carries close to 100% mortality and may be more common in children. Management consists of aggressive measures to maintain ICP < 22 mm Hg and CPP > 60-70 mm Hg.[25] (whether 60 or 70 is the optimal minimum for CPP is unclear). See ICP treatment threshold (p. 1047)
2. true cerebral edema: classically at autopsy these brains “weep fluid.”[26] Both vasogenic and cytotoxic cerebral edema (p. 90) can occur within hours of head injury[26,27] and when indicated may be treated with decompressive craniectomy (p. 1071)

61.2.4 Diffuse axonal injury (DAI) (AKA diffuse axonal shearing)

A *primary* lesion of rotational acceleration/deceleration head injury.[28] In its severe form, hemorrhagic foci occur in the corpus callosum and dorsolateral rostral brainstem with microscopic evidence of diffuse injury to axons (axonal retraction balls, microglial stars, and degeneration of white matter fiber tracts). Often cited as the cause of prolonged loss of consciousness in patients rendered immediately comatose following head injury in the absence of a space occupying lesion on CT[29] (although DAI may also be present with subdural[30] or epidural hematomas[31]).

May be diagnosed clinically when loss of consciousness (coma) lasts > 6 hours in absence of evidence of intracranial mass or ischemia.

DAI may be graded clinically as shown in ▶ Table 61.6, or histologically as in ▶ Table 61.7.

Table 61.6 Clinical grading of diffuse axonal injury (DAI)

DAI grade	Description
mild	coma > 6–24 hrs, followed by mild-to-moderate memory impairment, mild-to-moderate disabilities
moderate	coma > 24 hrs, followed by confusion & long-lasting amnesia. Mild-to-severe memory, behavioral, and cognitive deficits
severe	coma lasting months with flexor and extensor posturing. Cognitive, memory, speech, sensorimotor, and personality deficits. Dysautonomia may occur

Table 61.7 Histologic grading of diffuse axonal injury (DAI)[32]

DAI grade	Description
grade I	axonal injury in the white matter of the cerebral hemisphere, corpus callosum, brainstem and, less commonly, cerebellum
grade II	focal lesion[a] in the corpus callosum in addition to above
grade III	focal lesion[a] in the dorsolateral quadrant(s) of the rostral brainstem in addition to above

[a] focal lesions often can only be perceived microscopically

61.3 Posttraumatic hearing loss

61.3.1 Etiologies

It is well known that posttraumatic hearing loss can follow temporal bone fractures (p. 1064). Other etiologies have been more difficult to elucidate.[33] This section does not include iatrogenic trauma.

1. conductive hearing loss: injury distal to the cochlea. Classically associated with longitudinal temporal bone fractures. Hearing loss may be due to:
   a) disruption of the ossicular chain
   b) hemotympanum: may be diagnosed with otoscopic exam
2. sensorineural hearing loss. Hearing loss may be due to:
   a) injury to inner ear structures, e.g., cochlea
      1. injuries due to temporal bone fractures
      2. hypothesized "labyrinthine concussion" or "cochlear concussion" in cases without fracture
   b) injury to Cr.N. VIII
3. "central" hearing loss. Injuries to brain or brainstem structures including: inferior colliculi,[34] superficial siderosis of the brainstem following TBI, injury to bilateral frontal lobes and the left middle temporal gyrus[33]
4. mixed hearing loss: injury to any combination of the above

61.3.2 Epidemiology

► **Hearing loss with temporal bone fractures.** Hearing loss after temporal bone trauma in children occurs in > 80% of cases, and resolves in 75% without treatment.[35] Less common in adults, occuring in about 40% of head trauma.

► **Hearing loss without temporal bone fractures.** Estimate of the lower limit of incidence in a prospective study of mild TBI is 0.9%,[36] with an estimated upper limit ranging from 18-58% primarily from retrospective studies.[33]

61.3.3 Clinical

Hearing loss is usually readily apparent to a conscious patient. It may be accompanied by tinnitus which does not have prognostic significance.

In the comatose patient, the diagnosis is often delayed or not made at all. Brainstem autidtory evoked potentials may[37] or may not[34] be helpful in detection.

Dizziness and dysequilibrium may go unnoticed by the patient until they begin ambulating, but may be diagnosed clinically by the presence of nystagmus with the direction (the rapid phase) usually away from the affected ear.[35]

Determining the type of hearing loss is useful as surgical repair for conductive hearing loss can be helpful and may be performed any time, whereas sensorineural hearing loss is usually not responsive to treatment.[35]

Peripheral facial nerve palsy should be identified as it is essentially the only indication for possible *early* surgical intervention (p. 1064).

61.4 High-altitude cerebral edema

Acute high-altitude sickness (AHAS) is a systemic disorder that affects individuals usually within 6–48 hrs after ascent to high altitudes. Acute mountain sickness (AMS) is the most common form of AHAS, with symptoms of nausea, headache, anorexia, dyspnea, insomnia, and fatigue,[38] and is often assessed using the Lake Louise system.[39] The incidence is ≈ 25% at 7,000 feet and ≈ 50% at 15,000 feet. Other symptoms of AHAS include edema of feet and hands, and pulmonary edema (HAPE = high-altitude pulmonary edema). Ocular findings include retinal hemorrhages,[40] nerve fiber layer infarction, papilledema and vitreous hemorrhage.[41] Cerebral edema (HACE = high-altitude cerebral edema), usually associated with pulmonary edema, may occur in severe cases of AHAS. Symptoms of HACE include: severe headache, mental dysfunction (hallucinations, inappropriate behavior, reduced mental status), and neurologic abnormalities (ataxia, paralysis, cerebellar findings).

The unproven "tight-fit" hypothesis postulated that individuals with less compliant CSF systems (smaller ventricles and CSF spaces) were more vulnerable to AMS.[42] A small study of 10 volunteers[43] analyzing CT scans before ascent and symptoms showed a trend that supports the hypothesis.

Prevention: gradual ascent, 2–4 day acclimatization at intermediate altitudes (especially to include sleeping at these levels), avoidance of alcohol or hypnotics.

Treatment of cerebral edema: immediate descent and oxygen (6–12 L/min by NC or face-mask) are recommended. Dexamethasone 8 mg PO or IV followed by 4 mg q 6 hrs may help temporize.

61.5 Traumatic cervical artery dissections

61.5.1 General information

Cervical arterial dissections are a subset of cervical cerebrovascular injuries as shown below.

Cervical cerebrovascular injuries:

- penetrating injury (p. 1219)
- traumatic dissection: the subject of this chapter
  - due to blunt trauma
  - due to stretching: e.g., from neck hyperextension or therapeutic spinal manipulation
  - iatrogenic: dissection caused by intimal tear from angiography catheters
- traumatic compression or occlusion
  - kinking from malalignment: e.g., with cervical fracture-dislocation
  - compression by bone fragments: e.g., by fractures through foramen transversarium

This chapter deals with traumatic cervical artery dissections. There is significant overlap with spontaneous cerebrovascular arterial dissections (p. 1576); however, features that are more pertinent to posttraumatic dissections are covered here.

Optimal screening, diagnostic and treatment methods are controversial. A 13% mortality rate is considered low. Nearly one-third of patients are not treatable.

61.5.2 Epidemiology

Incidence: 1–2% of blunt trauma patients[44] (among those who stayed > 24 hrs in a trauma hospital the incidence was 2.4%[44]). In pediatric patients identified with BCVI, 69% were located in the intracranial ICA, 23% in the extracranial ICA, and 6% in the VA.[45]

61.5.3 Risk factors

Traumatic risk factors for blunt cerebrovascular injury (BCVI) are shown in ▶ Table 61.8. Risk factors not directly related to the type of trauma include fibromuscular dysplasia, where dissections may follow minor injuries because of increased susceptibility of the vessels. BCVI can occur even in the absence of identifiable risk factors.[44]

Table 61.8 Traumatic factors with high risk for BCVI[46,47]

- severe cervical hyperextension with rotation or hyperflexion
- high energy transfer mechanism associated with:
  - displaced mid face fracture: Le Fort fracture type II or III (p. 1067)
  - basilar skull fracture involving carotid canal
- TBI consistent with DAI and GCS < 6
- cervical vertebral body or transverse foramen fracture, subluxation, or ligamentous injury at any level
- any fracture involving C1–3
- near hanging with anoxic brain injury
- clothesline-type injury or seat belt abrasion with significant cervical swelling, pain, or mental status changes

61.5.4 Presentation

Signs and symptoms of BCVI are shown in ▶ Table 61.9.

Table 61.9 Signs & symptoms of BCVI[47]

- arterial hemorrhage from neck/nose/mouth (? go to O.R.)
- cervical bruit in pt < 50 yrs old
- expanding cervical hematoma
- focal neurologic deficit: TIA, Horner syndrome, hemiparesis, VBI
- neurologic deficit inconsistent with head CT
- stroke on CT or MRI

61.5.5 Evaluation of patients with risk factors or signs/symptoms of BCVI

▶ **Imaging findings.** Briefly, imaging findings with dissection may include: filling defect/luminal stenosis (▶ Fig. 61.2), occlusion, extravassation of contrast outside the normal lumen. See detailed list (p. 1578).

Dissection is graded as shown in ▶ Table 61.10 (AKA the "Denver grading scale").

▶ **Imaging protocol.** The following is an adaptation of the guidelines of the Western Trauma Association flow chart[47] (including footnotes!) into an outline format. Their recommendations are based on observational studies and expert opinion (no Class I data was available).

NB: CTAs on scanners with ≥ 16 detectors (16-slice multidetector CT angiography (16MD-CTA)) have an accuracy near 99%[49] & equivalent predictive value to catheter cerebral angiogram. MRA[50,51] and ultrasound[52,53] are not considered adequate for BCVI screening. If 16MD-CTA is not available, then catheter angiography is recommended.

1. 16MD-CTA should be obtained as follows:
   a) emergently in patients with signs/symptoms of BCVI (▶ Table 61.9)
   b) *asymptomatic* patients with risk factors (▶ Table 61.8) for BCVI:
      - if the presence of BCVI would alter therapy (e.g., no contraindication to heparin) then 16MD-CTA should be done within 12 hours if possible
      - if heparin is contraindicated due to associated injuries, timing of 16MD-CTA is determined by patient stability
2. if the 16MD-CTA is equivocal, or if it is negative but clinical suspicion remains high: a catheter arteriogram should be done (otherwise, if negative: stop)
3. if the 16MD-CTA or catheter arteriogram is abnormal (see positive findings (p. 1578)):
   a) determine the BCVI grade (▶ Table 61.10)[48]
   b) proceed with grade-based management (see below)

61.5.6 Management of documented BCVI

Antiplatelet therapy is as effective in preventing stroke as anticoagulation for cerebrovascular dissection.[54,55]

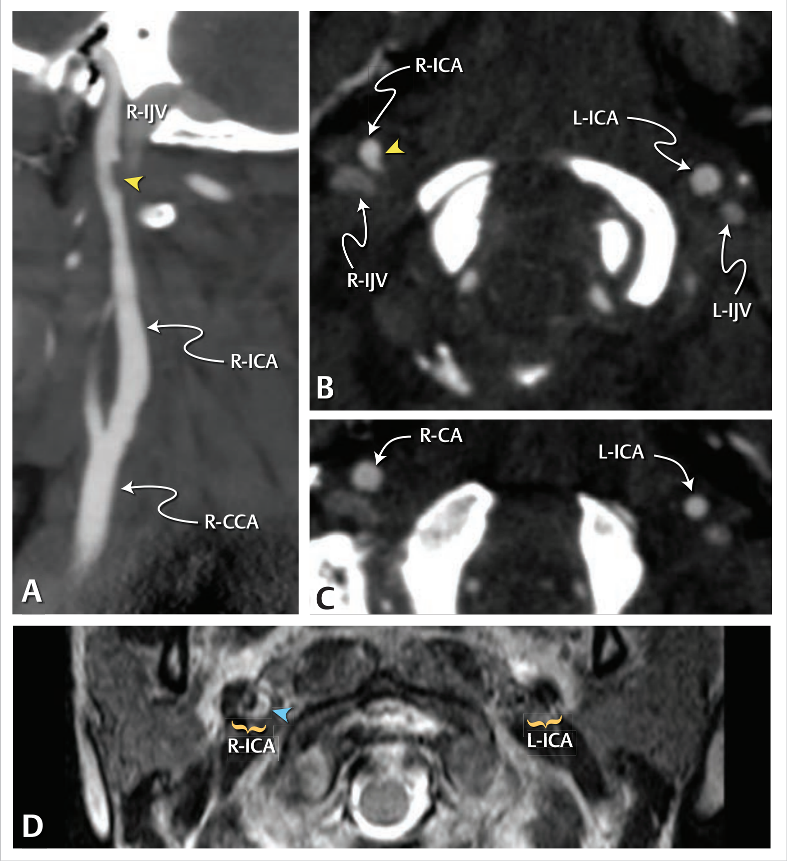

Fig. 61.2 Denver grade II focal dissection (*yellow arrowheads*) with 25% luminal stenosis of the right internal carotid artery at the level of C1 in a 27-year-old woman following a motor vehicle accident in which she also sustained atlanto-occipital dislocation that was subsequently operated.
Image: CTA, A: sagittal, B: axial through the dissection (note that the right ICA is not round, unlike the left ICA), C: axial just above the dissection to illustrate that the right ICA has returned to a round configuration which it also had below the dissection (not shown), D: T2 axial MRI through the dissection showing the “crescent sign” (*blue arrowhead*) with hematoma in the wall of the right ICA with narrowing of the lumen.
Abbreviations: CCA = common carotid artery, ICA = internal carotid artery, IJV = internal jugular vein, L = left, R= right.

Table 61.10 BCVI grading scale[48] (“Denver grading scale”)

Grade	Description
I	luminal irregularity with < 25% stenosis
II	≥ 25% luminal stenosis or intraluminal thrombus or raised intimal flap
III	pseudoaneurysm
IV	occlusion
V	transection with free extravasation

▶ **Grade specific therapy.** Using the Denver BCVI grade (▶ Table 61.10):

- Grade I & II
    - most resolve on their own
    - even though there might be a slight benefit of heparin over aspirin for low grade injuries, due to the low overall risk the general trend is to treat these with aspirin
- Grade III
    - anticoagulate with heparin. Rationale: heparin & aspirin are roughly equivalent for Grade III; however, most will need to be restudied in 7–10 days and heparin is easier to stop for an angio
    - repeat angiogram or 16MD-CTA 7–10 days post-injury. See below for subsequent management
- Grade IV: endovascular occlusion to prevent embolization
- Grade V: highly lethal injury
    - accessible lesions should be considered for urgent surgical repair (anecdotal)
    - inaccessible lesions (the majority): incomplete transection may be amenable to endovascular stenting with concurrent antithrombotics; complete transections should be ligated (or occluded endovascularly)

For Grade III repeat 16MD-CTA or catheter angiography 7–10 days post injury to assess healing.[56] Results:

1. lesion healed: discontinue anticoagulation
2. non-healed lesions:
    a) consider endovascular stenting “with caution” for severe luminal narrowing or expanding pseudoaneurysm (controversial: results have been mixed – favorable[54] and unfavorable[57])
    b) transition from heparin to aspirin (75–150 mg/d) alone
    c) repeat 16MD-CTA or catheter angiography 3 months post injury (rationale: most heal with canalization in 6 wks). Results:
        1. healed lesion: consider discontinuing aspirin
        2. non-healed: optimal drug and duration is not known. Recommendation[47]: lifelong antiplatelet therapy with either aspirin or clopidogrel. Dual therapy is used for acute coronary syndromes and following angioplasty (± stenting) but is not recommended in patients who have had a stroke or TIA[58]

Heparinization:

When anticoagulation is employed, perform a baseline PTT and then begin heparin drip 15 U/kg/hr IV. Repeat PTT after 6 hours, and titrate to PTT = 40–50 seconds.

Trauma contraindications to anticoagulation: patients that are actively bleeding, have potential for bleeding, or in whom the consequences of bleeding are severe. Specific examples include: liver and spleen injuries, major pelvic fractures, and intracranial hemorrhage.

Dissection-related anticoagulation risks include: extension of the medial hemorrhage (with possible SAH), and intracerebral hemorrhage (conversion of pale infarct to hemorrhagic).

61.5.7 Carotid artery blunt injuries

General information

See general information related to cerebral arterial dissections and spontaneous dissections (p. 1576). For evaluation and management, see above.

This section considers blunt (i.e., nonpenetrating) specifically related to ICA dissection. Neck hyperextension with lateral rotation is a common mechanism of injury, and is thought to stretch the ICA over the transverse processes of the upper cervical spine. In posttraumatic dissection, ischemic symptoms are the most common.[59]

Etiologies:

1. following MVAs: the most common etiology
2. attempted strangulation[60]
3. spinal manipulation therapy: VA dissections are more common than ICA

Most carotid dissections start ≈ 2 cm distal to the ICA origin.

Clinical

The risk of stroke increases with increasing grade for ICA injuries (▶ Table 61.11). This is not true for VA injuries.

Initially, there may be no neurologic sequelae; however, progressive thrombosis, intramural hemorrhage, or embolic phenomenon may develop in a delayed fashion. The distribution of time delays following trauma to time of presentation is shown in ▶ Table 61.12 (the majority are evident within the first 24 hours).

Table 61.11 Risk of stroke with ICA dissection

Grade[a]	Description	Stroke risk
I	stenosis < 25%	3%
II	stenosis > 25%	11%
III	pseudoaneurysm	44%
IV	occlusion	uniformly lethal

[a] for grading, see ▶ Table 61.10

Table 61.12 Time to presentation after non-penetrating trauma

Time	% of cases
0–1 hours	6–10
1–24 hours	57–73
after 24 hours	17–35

Management

See Management of documented BCVI (p. 1029).

Outcome

Natural history is not well known. Many patients with minor symptoms may not present and presumably do well. In one series, 75% of patients returned to normal, 16% had a minor deficit, and 8% had a major deficit or died.[61]

Grade I injuries: 70% heal with or without heparin. 25% will persist. 4–12% will progress to more severe grade. Data suggests that anticoagulation reduces the risk of progression.[46]

Grade II: ≈ 70% progress to more severe grade even with heparin therapy.

Grades III & IV: most persist.

61.5.8 Vertebral artery blunt injuries

General information

See anatomy of vertebral artery segments (p. 80).

Blunt vertebral artery injury (BVI) is very rare, being found in 0.5–0.7% of patients with blunt injuries with aggressive screening.[62] It may produce vertebrobasilar insufficiency (VBI) or posterior circulation stroke. Fractures through the foramen transversarium, facet fracture-dislocation, or vertebral subluxation are frequently identified in patients with BVI[46,63,64] (overall incidence increases to 6% in the presence of cervical fracture or ligamentous injury[62]).

Etiologies

While motor vehicle accidents are the most common mechanism of injury, any trauma that can injure the C-spine can cause BVI (diving accidents, spinal manipulation…).

1. automobile accidents
2. spinal manipulation therapy (SMT): including chiropractic[65] or similar, which comprise 11 of 15 case reports reviewed by Caplan et al.[66] VA dissections were independently associated with SMT within 30 days in multivariate analysis (odds ratio = 6.62, 95% CI 1.4 to 30)[67]
3. sudden head turning
4. direct blows to the back of the neck[66]

Stroke from BVI

The Denver grade of the dissection in BVI does not correlate with risk of stroke or mortality (as it does with ICA dissection).[68] Unlike with carotid injuries, there is rarely a premonitory "warning" TIA. Time from injury to stroke: mean 4 days (range: 8 hours-12 days).

Evaluation

When BVI is identified, it is critical to assess the status of the contralateral VA.

Practice guideline: Vertebral artery blunt injuries

Evaluation

Level I[69]

- Patients meeting the "Denver Screening Criteria" (symptoms shown in ▶ Table 61.9 or risk factors shown in ▶ Table 61.8) should undergo 16MD-CTA to screen for BVI

Level III[69]

- Catheter angiogram is recommended in select patients after blunt cervical trauma if 16MD-CTA is not available, especially if concurrent endovascular intervention is a consideration.
- MRI is recommended for BVI after blunt cervical trauma in patients with incomplete SCI or vertebral subluxation injuries.

Treatment

Practice guideline: Vertebral artery blunt injuries

Treatment

Level III[69]

- No specific guidelines were made among treatment options (anticoagulation, antiplatelet therapy, or no treatment)
- The role of endovascular therapy for BVI has not been defined

Strokes were more frequent in patients with BVI who were not treated initially with IV heparin despite an asymptomatic BVI.[46] However, based on historical controls, it is not clear if either screening or treatment improves overall outcome.[62]

Recommendations: treat all BVI with aspirin. Restudy chronic occlusion in 3 months.

Treatment options include endovascular stenting when amenable. This can restore near-normal flow, but long-term results are lacking.[70] Also, stenting requires ≥≈ 3 months of antiplatelet therapy which is contraindicated in some situations.

Outcome

Overall mortality with unilateral BVI ranges from 8–18%[68] which is lower than with ICA dissections (17–40%). Bilateral VA dissection appears highly fatal.

62 Neuromonitoring in Head Trauma

62.1 General information

This section considers neuromonitoring instrumentation that can be done primarily at the patient's bedside, and therefore does not include CT perfusion studies, PET scans…. The bulk of neuromonitoring literature deals with intracranial pressure (ICP). Other parameters that can be monitored include: jugular venous oxygen monitoring (p. 1045), regional CBF (p. 1046), brain tissue oxygen tension (p. 1045), and brain metabolites (pyruvate, lactate, glucose…) (p. 1046).

The role of adjunctive monitoring is currently unknown. Unanswered questions include: should neuromonitoring be disease specific (e.g., is SAH different from TBI), which monitors provide additional unique information, what are the critical values of the monitored entity, and what interventions should be undertaken to correct abnormalities?

62.2 Intracranial pressure (ICP)

62.2.1 Background

Intracranial pressure (ICP) is discussed in this section on trauma because of the close relationship between elevated ICP and brain damage from head injury. However, factors involved in diagnosing and treating intracranial hypertension (IC-HTN) also may pertain (with modifications) to brain tumors, dural sinus thrombosis, etc.

62.2.2 Cerebral perfusion pressure (CPP) and cerebral autoregulation

Secondary brain injury (i.e., following the initial trauma) is attributable in part to cerebral ischemia (see Secondary injury (p. 1000)). The critical parameter for brain function and survival is not actually ICP, rather it is adequate cerebral blood flow (CBF) to meet $CMRO_2$ demands (see discussion of CBF & $CMRO_2$ (p. 1536)). CBF is difficult to quantitate, and can only be measured continuously at the bedside with specialized equipment and difficulty.[1] However, CBF depends on cerebral perfusion pressure (CPP), which is related to ICP (which is more easily measured) as shown in Eq (62.1).

$$\begin{aligned}&\{\text{cerebral perfusion pressure}\} = \{\text{mean arterial pressure}^*\} - \{\text{intracranial pressure}\}\\&\text{or, expressed in symbols}\\&\text{CPP} = \text{MAP}^* - \text{ICP}\end{aligned} \tag{62.1}$$

*note: the actual pressure of interest is the mean carotid pressure (MCP) which may be approximated as the MAP with the transducer zeroed ≈ at the level of the foramen of Monro.[2]

As ICP becomes elevated, CPP is reduced at any given MAP. Normal adult CPP is > 50 mm Hg. Cerebral autoregulation is a mechanism whereby over a wide range, large changes in systemic BP produce only small changes in CBF. Due to autoregulation, CPP would have to drop below 40 in a normal brain before CBF would be impaired.

In the head injured patient, older recommendations were to maintain CPP ≥ 70 mm Hg (due to increased cerebral vascular resistance) & ICP < 20 mm Hg.[3] However, recent evidence suggests that elevated ICP (≥ 22 mm Hg) may be more detrimental than changes in CPP (as long as CPP is > 60-70 mm Hg[4])[5] (higher levels of CPP were not protective against significant ICP elevations[6]).

62.2.3 ICP principles

The following are approximations to help simplify understanding ICP (these are only models, and as such are not entirely accurate):

1. *normal* intracranial constituents (and approximate volumes):
   a) brain parenchyma (which also contains extracellular fluid): 1400 ml
   b) cerebral blood volume (CBV): 150 ml
   c) cerebrospinal fluid (CSF): 150 ml
2. these volumes are contained in an inelastic, completely closed container (the skull)
3. pressure is distributed evenly throughout the intracranial cavity (in reality, pressure gradients exist[7,8])

4. the modified **Monro-Kellie doctrine**[9] states that the sum of the intracranial volumes (CBV, brain, CSF, and other constituents (e.g., tumor, hematoma…)) is constant, and that an increase in any one of these must be offset by an equal decrease in another. If the pressure from one intracranial constituent increases (as when that component increases in volume), it causes the pressure inside the skull (ICP) to increase. This increased ICP will act to force one or more of the other constituents out through the foramen magnum (FM) (the only true effective opening in the intact skull) or though a craniectomy defect (after decompressive craniectomy surgery) until a new ICP equilibrium is established. The craniospinal axis can buffer small increases in volume with no change or only a slight increase in ICP. If the expansion continues, then the new equilibrium will be at a higher ICP. The result:
    a) at pressures slightly above normal, if there is no obstruction to CSF flow (obstructive hydrocephalus), CSF can be displaced from the ventricles and subarachnoid spaces and exit the intracranial compartment via the FM
    b) intravenous blood can also be displaced through the jugular foramina via the IJVs
    c) as ICP continues to rise above the intracranial arterial pressure, arterial blood (part of CBV) is displaced and further entry of arterial blood into the cranium is impaired. When ICP reaches the mean arterial pressure, arterial blood will be unable to enter the skull through the FM, producing complete cessation of blood flow to the brain, with resultant massive infarction
    d) increased brain edema, or an expanding mass (e.g., hematoma) can push brain parenchyma downward into the foramen magnum (cerebral herniation) although brain tissue cannot actually exit the skull

62.2.4 Normal ICP

The normal range of ICP varies with age. Values for pediatrics are not well established. Guidelines are shown in ▶ Table 62.1.

Table 62.1 Normal ICP

Age group	Normal range (mm Hg)
adults and older children[a]	< 10–15
young children	3–7
term infants[b]	1.5–6

[a] the age of transition from “young” to “older” child is not precisely defined
[b] may be subatmospheric in newborns[10]

62.2.5 Intracranial hypertension (IC-HTN)

General information

Traumatic IC-HTN may be due to any of the following (alone or in various combinations):

1. cerebral edema
2. hyperemia: the normal response to head injury.[11] Possibly due to vasomotor paralysis (loss of cerebral autoregulation). May be more significant than edema in raising ICP (p. 1084) [12]
3. traumatically induced masses
    a) epidural hematoma
    b) subdural hematoma
    c) intraparenchymal hemorrhage (hemorrhagic contusion)
    d) foreign body (e.g., bullet)
    e) depressed skull fracture
4. hydrocephalus due to obstruction of CSF absorption or circulation
5. hypoventilation (causing hypercarbia → vasodilatation)
6. systemic hypertension (HTN)
7. venous sinus thrombosis
8. increased muscle tone and Valsalva maneuver as a result of agitation or posturing → increased intrathoracic pressure → increased jugular venous pressure → reduced venous outflow from the head
9. sustained posttraumatic seizures (status epilepticus)

A *secondary increase in ICP* is sometimes observed 3–10 days following the trauma, and may be associated with a worse prognosis.[13] Possible causes include:

1. delayed hematoma formation
   a) delayed epidural hematoma (p. 1075)
   b) delayed acute subdural hematoma (p. 1081)
   c) delayed traumatic intracerebral hemorrhage[14] (or hemorrhagic contusions) with perilesional edema: usually in older patients, may cause sudden deterioration. May become severe enough to require evacuation (p. 1072)
2. cerebral vasospasm[15]
3. severe adult respiratory distress syndrome (ARDS) with hypoventilation
4. delayed edema formation: more common in pediatric patients
5. hyponatremia

Clinical presentation—Cushing's triad

The classic clinical presentation of IC-HTN (regardless of cause) is Cushing's triad which is shown in ▶ Table 62.2. However, the full triad is only seen in ≈ 33% of cases of IC-HTN.

Patients with significant ICP elevation due to trauma, brain masses (tumor), or hydrocephalus (but paradoxically not with pseudotumor cerebri) will usually be obtunded.

Table 62.2 Cushing's triad with elevated ICP

1. hypertension
2. bradycardia
3. respiratory irregularity

CT scan and elevated ICP

Whereas CT findings may be correlated with a risk of IC-HTN, no combination of CT findings has been shown to allow accurate estimates of actual ICP. 60% of patients with closed head injury and an abnormal CT will have IC-HTN.[16] (**Note:** "abnormal" CT: demonstrates hematomas (EDH, SDH or ICH), contusions,[16] compression of basal cisterns (p. 1109), herniation or swelling[17,18]).

Only 13% of patients with a *normal* CT scan will have IC-HTN.[16] However, patients with a normal CT AND 2 or more risk factors identified in ▶ Table 62.3 will have ≈ 60% risk of IC-HTN. If only 1 or none are present, ICP will be increased in only 4%.

Table 62.3 Risk factors for IC-HTN with a normal CT

- age > 40 yrs
- SBP < 90 mm Hg
- decerebrate or decorticate posturing on motor exam (unilateral or bilateral)

62.2.6 ICP monitoring

Indications for ICP monitoring

Practice guideline: Indications for ICP monitoring

For salvageable patients with severe traumatic brain injury (GCS ≤ 8 after cardiopulmonary resuscitation)

Level II[18]: with an abnormal admitting brain CT (**note**: abnormal" CT: demonstrates hematomas (EDH, SDH or ICH), contusions,[16] compression of basal cisterns (p. 1109), herniation, or swelling[17,18])

Level III[18]: with a *normal* admitting brain CT, but with ≥ 2 of the following risk factors for IC-HTN:

- age > 40 yrs
- SBP < 90 mm Hg
- decerebrate or decorticate posturing on motor exam (unilateral or bilateral)

1. ★ neurologic criteria: see **Practice guideline: Indications for ICP monitoring** (p. 1038)
   a) some centers monitor patients who don't follow commands. Rationale: patients who follow commands (GCS ≥ 9) are at low risk for IC-HTN, and one can follow sequential neurologic

exams in these patients and institute further evaluation or treatment based on neurologic deterioration
   b) some centers monitor patients who don't localize, and follow neuro exam on others
2. multiple systems injured with altered level of consciousness (especially where therapies for other injuries may have deleterious effects on ICP, e.g., high levels of PEEP or the need for large volumes of IV fluids or the need for heavy sedation)
3. with traumatic intracranial mass (EDH, SDH, depressed skull fracture…)
   a) a physician may choose to monitor ICP in some of these patients[17,19]
   b) post-op, subsequent to removal of the mass
4. non-traumatic indications for ICP monitoring: some centers monitor ICP in patients with acute fulminant liver failure with an INR > 1.5 and Grade III of IV coma. A *subarachnoid bolt* may be inserted after administration of factor VII 40 mcg/kg IV over 1–2 minutes (the bolt is inserted as soon as possible (usually within 15 minutes and no more than 2 hours after administration)) without significant risk of hemorrhage.[20] All patients were treated with hypothermia; other ICP treatment measures were used for refractory IC-HTN

Contraindications (relative)

1. "awake" patient: monitor usually not necessary, can follow neuro exam
2. coagulopathy (including DIC): frequently seen in severe head injury. If an ICP monitor is essential, take steps to correct coagulopathy (FFP, platelets…) and consider *subarachnoid bolt* or *epidural monitor* (an IVC or intraparenchymal monitor is contraindicated). See recommended range of PT or INR (p. 164).

Duration of monitoring

D/C monitor when ICP is normal × 48–72 hrs after withdrawal of ICP therapy. Caution: IC-HTN may have delayed onset (often starts on day 2–3, and day 9–11 is a common second peak, especially in peds). Also see delayed deterioration (p. 1000). Avoid a false sense of security imparted by a normal early ICP.

Complications of ICP monitors

General information

See ▶ Table 62.4 for a summary of complication rates for various types of monitors.[3]
1. infection: see below
2. hemorrhage[3]: overall incidence is 1.4% for all devices (see ▶ Table 62.4 for breakdown). The Angioma Alliance definition of hemorrhage (p. 1527) [23] is recommended. Risk of significant hematoma requiring surgical evacuation is ≈ 0.5–2.5%[16,24,25]
3. malfunction or obstruction: with fluid coupled devices, higher rates of obstruction occur at ICPs > 50 mm Hg
4. malposition: 3% of IVCs require operative repositioning

Infection with ICP monitors

Colonization of the monitoring device is much more common than clinically significant infection (ventriculitis or meningitis). See ▶ Table 62.4 for colonization rates. Fever, leukocytosis and CSF

Table 62.4 Complication rates with various types of ICP monitors

Monitor type	Bacterial colonization[a]	Hemorrhage	Malfunction or obstruction
IVC	ave: 10–17% range[21,22]: 0–40%	1.1%	6.3%
subarachnoid bolt	ave: 5% range: 0–10%	0	16%
subdural	ave: 4% range: 1–10%	0	10.5%
parenchymal	ave: 14% (two reports, 12% & 17%)	2.8%	9–40%

[a] some studies report this as infection, but do not distinguish between clinically significant infection and colonization of ICP monitor

pleocytosis have low predictive value (CSF cultures are more helpful). Range of reported infection rates: 1–27%.[26]

Practice guideline: Infection prophylaxis with ICP monitors

Level III[27]: neither prophylactic antibiotics nor routine ventricular catheter exchange is recommended to reduce infection

Level III[5 (p 100)]: antimicrobial-impregnated catheters may be considered to prevent EVD related infections

Identified risk factors for infection include[26,28,22,29]:

1. intracerebral, subarachnoid or intraventricular hemorrhage
2. ICP > 20 mm Hg
3. duration of monitoring: contradictory results in literature. One prospective study in 1984 found an increased risk with monitor duration > 5 days (infection risk reaches 42% by day #11).[24,28] Another found no correlation with monitoring duration.[30] A retrospective analysis[22] found a non-linear increase of risk during the first 10–12 days, after which the rate diminished rapidly
4. neurosurgical operation: including operations for depressed skull fracture
5. irrigation of system
6. leakage around IVCs
7. open skull fractures (including basilar skull fractures with CSF leak)
8. other infections: septicemia, pneumonia

Factors *not* associated with increased incidence of infection:

1. insertion of IVC in neuro intensive care unit (instead of O.R.)
2. previous IVC
3. drainage of CSF
4. use of steroids

Treatment of infection

Removal of device if at all possible (if continued ICP monitoring is required consideration may be given to inserting a monitor at another site) and appropriate antibiotics.

Types of monitors

1. intraventricular catheter (IVC): AKA external ventricular drainage (EVD), connected to an external pressure transducer via fluid-filled tubing. The standard by which others are judged (also below; **note**: other options for IVCs utilize transducers tipped with fiberoptic or strain gauge devices, which are located within the intraventricular catheter; in this discussion, “IVC” does not refer to this type)
   a) advantages:
      - most accurate (can be recalibrated to minimize measurement drift)[31]
      - lower cost
      - in addition to measuring pressure, allows therapeutic CSF drainage (may help reduce ICP directly, and may drain particulate matter, e.g., blood breakdown products after SAH, that could occlude arachnoid granulations[32])
   b) disadvantages
      - may be difficult to insert into compressed or displaced ventricles
      - obstruction of the fluid column (e.g., by blood clot, or by coaptation of the ependymal lining on the catheter as the ventricle collapses with drainage) may cause inaccuracy
      - some effort is required to check and maintain function, e.g., IVC problems (p. 1042) and IVC trouble shooting (p. 1043)
      - transducer must be consistently maintained at a fixed reference point relative to patient’s head (must be moved as HOB is raised/lowered)
2. intraparenchymal monitor (e.g., Camino labs or Honeywell/Phillips[33,34]): similar to IVC but more expensive. Some are subject to measurement drift,[35,36] others may not be[37]

3. *less accurate* monitors
   a) subarachnoid screw (bolt): risk of infection 1%, rises after 3 days. At high ICPs (often when needed most) surface of brain may occlude lumen → false readings (usually lower than actual, may still show ≈ normal waveform)
   b) subdural: may utilize a fluid coupled catheter (e.g., Cordis Cup catheter), fiberoptic tipped catheter, or strain gauge tipped catheter
   c) epidural: may utilize a fluid coupled catheter, or fiberoptic tipped catheter (e.g., Ladd fiberoptic). Accuracy is questionable
   d) in infants, one can utilize an open anterior fontanelle (AF):
      - fontanometry[38]: probably not very accurate
      - applanation principle: may be used in suitable circumstances (viz.: if the fontanelle is concave with the infant upright, and convex when flat or head down) to estimate the ICP within 1 cm H_2O.[10] The infant is placed supine, and the AF is visualized and palpated while the head is raised and lowered. When the AF is flat, the ICP equals atmospheric pressure, and ICP can be estimated in cm H_2O as the distance from the AF to the point where the venous pressure is 0 (for a recumbent infant, the midpoint of the clavicle usually suffices). If the AF is not concave with the infant erect, then this method cannot be used, because either the ICP exceeds the distance from the AF to the venous zero point, or the scalp may be too thick

Conversion factors between mm Hg and cm H_2O are shown in Eq (62.2) and Eq (62.3) (the density of mercury is 13.6 times that of water, and CSF is fairly close to water).

$$1 \text{ mm Hg [torr]} = 1.36 \text{ cm } H_2O \tag{62.2}$$

$$1 \text{ cm } H_2O = 0.735 \text{ mmHg [torr]} \tag{62.3}$$

Intraventricular catheter (IVC)

Insertion technique

For technique to place catheter in frontal horn, see Kocher's point (p. 1821). The right side is usually used unless specific reasons to use the left are present (e.g., blood clot in right lateral ventricle which might occlude IVC).

Set-up

▶ Fig. 62.1 shows a typical external ventricular drainage (EVD) system/ventriculostomy ICP monitor. Not every system will have the same components (some may have less and some may have more). Note that the effect of having an opening on the top of the drip chamber (through an air-filter) is the same as having the drip nozzle open to air, and therefore as long as this filter is not wet or plugged the pressure in the IVC is regulated by the height of the nozzle (as read on the pressure scale; note that the "0" is level with the nozzle).

The external auditory canal (EAC) is often used as a convenient external landmark for "0" (approximates the level of the foramen of Monro). In ▶ Fig. 62.1 the drip chamber is illustrated at 8 cm above the EAC.

Normal functioning of the IVC system

The system should be checked for proper functioning at least every 2–4 hours, and any time there is a change in: ICP (increase or decrease), neuro exam, or CSF output (for systems open to drainage).

1. check for presence of good waveform with respiratory variations and transmitted pulse pressures
2. IVCs: to check for patency, open the system to drain and lower the drip chamber below level of head and observe for 2–3 drops of CSF (normally do not allow more than this to drain)
3. for systems open to drainage:
   a) volume of CSF in drip chamber should be indicated every hour with a mark on a piece of tape on the drip chamber, and the volume should increase with time unless ICP is less than the

drainage tube clamp
drainage port

Fig. 62.1 Medtronic® ventricular drainage system/ICP monitor.

height of the drip chamber (in practice, under these circumstances the system would usually not be left open to drainage).

NB: the maximum expected output from a ventriculostomy would be ≈ 450–700 ml per day in a situation where none of the produced CSF is absorbed by the patient. This is not commonly encountered. A typical amount of drainage would be ≈ 75 ml every 8 hrs

b) drip chamber should be emptied into drainage bag regularly (e.g., q 4 or 8 hours) and any time the chamber begins to get full (record volume)

4. in cases where there is a question whether the monitor is actually reflecting ICP, lowering the HOB towards 0° should increase ICP. Gentle pressure on both jugular veins simultaneously should also cause a gradual rise in ICP over 5–15 seconds that should drop back down to baseline when the pressure is released

IVC problems

The following represents some of the error or pitfalls that commonly occur with external ventricular drainage. Some also apply to ICP monitoring in general.

1. air filter on drip chamber gets wet (prevents air from passing through filter)
   a) result: fluid cannot drain freely into drip chamber (the pressure is no longer regulated by the height of the drip nozzle)
      - if the outflow from the drip chamber is clamped, then no flow at all is possible

      - if the clamp on the drip chamber outlet is open, then the pressure is actually regulated by the height of the nozzle in the *collection bag* and not the nozzle in the drip chamber
   b) solution: if a fresh filter is available, then replace the wet one. Otherwise one must improvise (with the risk of exposing the system to contamination): e.g., replace the wet filter with a filter from an IV set, or with a sterile gauze taped over the opening
2. air filter on collection bag gets wet: this will make it difficult to empty the drip chamber into the bag
   a) this is not usually an urgent problem unless the drip chamber is full and the collection bag is distended tensely with air
   b) the filter will dry out with time and will usually start to work again
   c) if it is necessary to empty the drip chamber before the filter is dry, then use sterile technique to insert a needle into the bag drainage port and decompress the bag of fluid and air
3. improper connections: a pressurized irrigation bag with or without heparinized solution should *never* be connected to an ICP monitor
4. changing position of head of bed: must move drip chamber up or down to keep it level with the same external landmarks (e.g., level of auditory canal):
   a) when open to drainage, this will assure the correct pressure will be maintained
   b) when opened to pressure transducer, will maintain correct zero
5. when open to drain, pressure reading from transducer is not meaningful: the pressure cannot exceed the height of the drip chamber in this situation (because at that point, fluid will drain off), and the opening to the “atmosphere” in the drip chamber will dampen the waveform
6. drip chamber falls to floor:
   a) overdrainage, possible seizures and/or subdural hematoma formation
   b) solution: securely tape chamber to pole, bed-rail…, check position regularly

IVC troubleshooting

See also IVC problems above.

► **IVC no longer works:**
1. manifestation of problem:
   a) dampening or loss of normal waveform
   b) no fluid drains into drip chamber (applies only when catheter has been opened to drain)
2. possible causes:
   a) occlusion of catheter proximal to transducer
      - slide clamp closed or stopcock closed
      - catheter occluded by brain particles, blood cells, protein
   b) IVC pulled out of ventricle
      - test: temporarily lower drip nozzle and watch for 2–3 drops CSF
      - solution:
        verify all clamps are open, and
        flush no more than 1.5 ml of non-bacteriostatic saline (AKA preservative-free saline) with very gentle pressure into ventricular catheter (NB: in elevated ICP the compliance of the brain is abnormally low and small volumes can cause large pressure changes).
        Note. If no return then brain or clot is probably plugging catheter. If it is known that the ventricles are ≈ completely collapsed then the IVC may be OK and CSF should still drain over time. Otherwise this is a non-functioning catheter, and if a monitor/drain is still indicated then a new catheter may need to be inserted (CT may be considered first if the status of the ventricles is not known). If catheter is clotted by intraventricular hemorrhage, rt-PA may sometimes be used (p. 1626) [39]

► **ICP waveform dampened.** Possible causes:
1. occlusion of catheter proximal to transducer: see above
2. IVC pulled out of ventricle: no fluid will drain
3. air in system:
   - solution: allow CSF to drain and expel air
   - caution: do not allow excessive amount of CSF to drain (may allow obstruction of catheter, subdural formation…). Do not inject fluid to flush air into brain
4. following decompressive craniectomy: due to the fact that the catheter is no longer in a closed space, this is a normal finding in this setting

Types of ICP waveforms

Normal waveforms

The normal ICP waveform (as occurs with normal blood pressure and in the absence of IC-HTN) as illustrated in ▶ Fig. 62.2 is rarely seen since ICP is usually monitored only when it is elevated. The origin of the variations seen in the normal tracing is somewhat in dispute. One explanation describes these two types of waveforms[40]:

1. small pulsations transmitted from the systemic blood pressure to the intracranial cavity
   a) large (1–2 mm Hg) peak corresponding to the arterial systolic pressure wave, with a small dicrotic notch
   b) this peak is followed by smaller and less distinct peaks
   c) followed by a peak corresponding to the central venous "A" wave from the right atrium
2. blood pressure pulsations are superimposed on slower respiratory variations. During expiration, the pressure in the superior vena cava increases, which reduces venous outflow from the cranium, causing an elevation in ICP. This may be reversed in mechanically ventilated patients, and is opposite to that in the lumbar subarachnoid space, which follows the pressure in the *inferior* vena cava

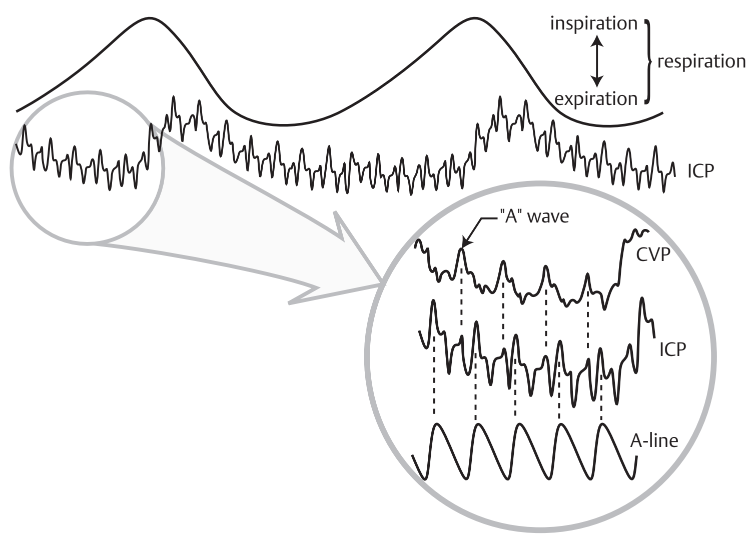

Fig. 62.2 Normal ICP waveform.

Pathological waveforms

As ICP rises and cerebral compliance decreases, the venous components disappear and the arterial pulses become more pronounced. In right atrial cardiac insufficiency, the CVP rises and the ICP waveform takes on a more "venous" or rounded appearance and the venous "A" wave begins to predominate.

A number of "pressure waves" that are more or less pathologic have been described. Currently, this classification is not considered to be of great clinical utility, with more emphasis being placed on recognizing and successfully treating elevations of ICP. Plateau waves will rarely be seen because they are usually aborted at the onset by instituting treatments outlined herein (p. 1046). A brief description of some of these waveforms is included here for general information[41]:

1. Lundberg A waves AKA plateau waves (of Lundberg, ▶ Fig. 62.3): ICP elevations ≥ 50 mm Hg for 5–20 minutes. Usually accompanied by a simultaneous increase in MAP (it is debated whether the latter is cause or effect)

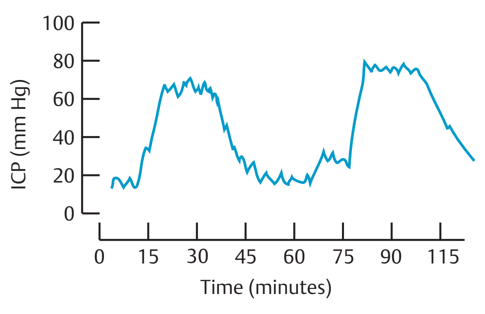

Fig. 62.3 Plateau waves (Lundberg A waves).

2. Lundberg B waves AKA pressure pulses: amplitude of 10–20 mm Hg is lower than A waves. Variation with types of periodic breathing. Last 30 secs–2 mins
3. Lundberg C waves: frequency of 4–8/min. Low amplitude C waves (AKA Traube-Hering waves) may sometimes be seen in the normal ICP waveform. High amplitude C-waves may be pre-terminal, and may sometimes be seen on top of plateau waves

62.3 Adjuncts to ICP monitoring

62.3.1 Jugular venous oxygen monitoring

Indications for SjVOs or $PbtO_2$ monitoring include the need for augmented hyperventilation (pCO_2 = 20–25) to control ICP. Parameters related to oxygen content of the blood in the jugular veins are global in nature and are insensitive to focal pathology. Requires retrograde placement of catheter near to the origin of the internal jugular vein at the base of the skull. Parameters that can be measured:

1. jugular venous oxygen saturation ($SjVO_2$): measured continuously with special fiberoptic catheter. Normal $SjVO_2$: ≥ 60%. Desaturations to < 50% suggest ischemia. Multiple desaturations (< 50%) or sustained (≥ 10 minutes) or profound desaturation episodes are associated with poor outcome.[42,43] Sustained desaturations should prompt an evaluation for correctable etiologies: kinking of jugular vein, anemia, increased ICP, poor catheter position, CPP < 60 mm Hg, vasospasm, surgical lesion, $PaCO_2$ < 28 mm Hg. High $SjVO_2$ > 75% may indicate hyperemia or infarcted tissue and is also associated with poor outcome[44]
2. jugular vein oxygen content (CVO_2). Requires intermittent sampling of blood
3. arterial-jugular venous oxygen content difference ($AVdO_2$)[45]: $AVdO_2$ > 9 ml/dl (vol%) probably indicates global cerebral ischemia,[46,47] while values < 4 ml/dl indicate cerebral hyperemia[48] ("luxury perfusion" in excess of the brain's metabolic requirement[47])

62.3.2 Brain tissue oxygen tension monitoring ($PbtO_2$)

Indications for SjVOs or $PbtO_2$ monitoring include the need for augmented hyperventilation (pCO_2 = 20–25) to control ICP. Monitored e.g., with Licox® probe. The likelihood of death increases with longer times of brain tissue oxygen tension ($p_{Bt}O_2$) < 15 mm Hg or even a brief drop of $PbtO_2$ < 6.[49] Initial $pBtO_2$ < 10 mm Hg for > 30 minutes correlates with increased risk of death or bad outcome.[50] Also, see **Practice guideline: Brain oxygen monitoring** (p. 1047).

Probe placement:

1. TBI: assumed to be a diffuse process, often placed on *least* injured side
2. SAH: placed in vascular distributions at greatest risk of vasospasm
   a) ACA (with ACA or AComA aneurysm): standard frontal placement (≈ 2–3 cm off midline on appropriate side)
   b) MCA (with ICA or MCA aneurysm): 4.5–5.5 cm off midline
   c) ACA-MCA watershed area: 3 cm lateral to midline
3. ICH: usually placed near the site of the hemorrhage

Effect of $pBtO_2$ monitoring/intervention on outcome: no randomized studies

1. in TBI[51]: goal was to maintain $pBtO_2 > 25$ mm Hg. Adding $pBtO_2$ monitoring resulted in improved outcome. May have been result of increased attentiveness ("Hawthorne effect")
2. in SAH[52]: a moving correlation coefficient (ORx) between CPP and $pBtO_2$ was used to label high ORx as disturbed autoregulation, and this value on post SAH days 5 & 6 had predictive value for delayed infarction

Management suggestions for $pBtO_2 < 15–20$ mm Hg:

1. consider jugular venous O_2 saturation monitor or lactate microdialysis monitor for confirmation
2. consider CBF study to determine generalizability of $pBtO_2$ monitor reading
3. treatment: proceed to each tier as needed
   a) tier 1
      - keep body temperature < 37.5 C
      - increase CPP to > 60 mm Hg (use fluids preferentially to pressors until CVP > 8 cm H_2O, then use pressors)
   b) tier 2
      - increase FiO_2 to 60%
      - increase $paCO_2$ to 45–50 mm Hg
      - transfuse PRBCs until Hgb > 10 g/dl
   c) tier 3
      - increase FiO_2 to 100%
      - consider increasing PEEP to increase PaO_2 if FiO_2 is at 100%
      - decrease ICP to < 10 mm Hg (drain CSF, mannitol, sedation…)

62.3.3 Bedside monitoring of regional CBF (rCBF)

Thermal diffusion flowmetry permits continuous rCBF monitoring by assessing thermal convection due to tissue blood flow. The probe tip is inserted into the *white matter* of the brain. Commercially available systems include Hemedex® monitoring system (Codman) utilizing the QFLOW 500® probe, which is ✖ not MRI compatible.

Probe placement: issues similar to those discussed for $pBtO_2$ (see above).

Readout:

1. K value (thermal conduction): range for white matter is 4.9–5.8 mW/cm-°C (the monitor suppresses CBF readings if the K value is outside this range)
   a) K < 4.9: the probe tip is probably out of the brain tissue or white matter—the probe should be *advanced* 1–2 mm
   b) K > 5.8 the tip is probably too deep, near a blood vessel, or in the ventricle or epidural or subdural space—the probe should be *retracted* 1–2 mm
2. CBF
   a) normal white matter: 18–25 ml/100 g-min
      - white matter CBF < 15: may indicate vasospasm or ischemia
      - white matter CBF < 10: may indicate infarction
   b) normal gray matter: 67–80 ml/100 g-min

Observational data: in a small study of SAH (n=5) and TBI (n=3)[53] there was good correlation between rCBF and $pBtO_2$ 91% of the time. Monitoring was not possible 36% of the time due to patient fever (wherein the system prevents monitoring).

62.3.4 Cerebral microdialysis

Compounds assayed include: lactate, pyruvate, lactate/pyruvate ratio, glucose, glutamate, urea and electrolytes including K^+ & calcium. Some observational data:

1. lactate levels increase during episodes of $SjVO_2$ desaturation[54]
2. decreased extracellular glucose was associated with increased mortality[55]

62.4 Treatment measures for elevated ICP

62.4.1 General information

This section presents a general protocol for treating documented (or sometimes clinically suspected) intracranial hypertension (IC-HTN). Guidelines promulgated by the Brain Trauma Foundation[3,56,57,58] are generally followed. Unless otherwise stated, guidelines are for adult patients (≥ 18 years of age).

62.4.2 Treatment thresholds

Intracranial pressure treatment thresholds

The optimal ICP at which to begin treatment is not known. Various cutoff values are used at different centers above which treatment measures for intracranial hypertension (IC-HTN) are initiated. Although 15, 20, and 25 have been quoted, the Brain Trauma Foundation guideline is ICP > 22 mm Hg[5] as shown in **Practice guideline: ICP treatment threshold** (p. 1047). ✖ Caution: patients can herniate even at ICP < 20[59] (depends on location of intracranial mass).

Rationale: ICP above 22 mm Hg was associated with increased mortality.[60] It is also possible that control may be better by treating early rather than waiting and trying to control higher ICPs or when plateau waves occur.[61]

Practice guideline: ICP treatment threshold

Level II[60 (p 172)]: treatment for IC-HTN should be initiated for **ICP > 22 mm Hg**

Level III[62]: the need for treatment should be based on ICP in combination with clinical examination & brain CT findings

Cerebral perfusion pressure (CPP)

The optimal value for CPP has yet to be determined. The threshold for ischemia is in the range of CPP < 50–60 mm Hg. **Practice guideline: Cerebral perfusion pressure issues** (p. 1047) outlines current recommendations regarding CPP.

Practice guideline: Cerebral perfusion pressure issues

Level II[63]: ✖ avoid aggressive use of fluids and pressors to maintain CPP (because of risk of adult respiratory distress syndrome (ARDS))

Level II[5]: the recommended target for **CPP is > 60-70 mm Hg** (whether 60 vs. 70 is optimal is unclear)

Level III[63]: ✖ avoid CPP < 50 mm Hg

Level III[63]: ancillary monitoring of CBF, oxygenation or metabolism assists CPP management

Brain oxygenation parameters

Suggestions for treatment thresholds are shown in **Practice guideline: Brain oxygen monitoring** (p. 1047). It remains to be determined which interventions are useful to achieve this, and whether this improves outcome.

Practice guideline: Brain oxygen monitoring

Level III[64]: jugular venous O_2 saturation < 50% or brain tissue oxygen tension ($PbtO_2$) < 15 mm Hg are treatment thresholds

62.4.3 ICP management protocol

Quick reference summary

▶ Table 62.5 summarizes a protocol for control of IC-HTN (below for details).

Dosages are given for an average adult, unless specified as mg/kg. Treatment may be initiated prior to insertion of a monitor if there is acute neurologic deterioration or clinical signs of IC-HTN, but continued treatment requires documentation of persistent IC-HTN.

For persistent IC-HTN consider “second tier” therapies (p. 1051).

Table 62.5 Summary of measures to control IC-HTN[a] Goals: ICP < 22 mm Hg, and CPP ≥ 60-70 mm Hg[5,60]

Step	Rationale/Remedy
GENERAL MEASURES (should be utilized routinely)	
elevate HOB to 30–45°	↓ ICP by enhancing venous outflow, but also reduces mean carotid pressure → no net change in CBF
keep neck straight, avoid neck constrictions (tight trach tape, tight cervical collar...)	constriction of jugular venous outflow causes ↑ ICP
avoid arterial hypotension (SBP < 90 mm Hg)	• hypotension reduces CBF • ℞: normalize intravascular volume, use pressors if needed
control hypertension if present	• ℞: nicardipine if not tachycardic • ℞: beta-blocker if tachycardic (labetalol, esmolol...) • ✖ avoid overtreatment → hypotension
avoid hypoxia ($PaO_2 < 60$ mm Hg or O_2 sat < 90%)	hypoxia may cause further ischemic brain injury ℞: maintain airway and adequate oxygenation
ventilate to normocarbia ($PaCO_2 = 35–40$ mm Hg)	✖ avoid prophylactic hyperventilation (p. 1052)
light sedation: e.g., codeine 30–60 mg IM q 4 hrs PRN	(same as heavy sedation, see below)
controversial: prophylactic hypothermia. If used, hold at target temp > 48 hrs	hypothermia → ↓ $CMRO_2$ – efficacy not rigorously proven (p. 1052)
unenhanced head CT scan for ICP problems[b]	rule out surgical condition
SPECIFIC MEASURES FOR IC-HTN	
proceed to successive steps if documented IC-HTN persists – each step is ADDED to the previous measure	
heavy sedation (e.g., fentanyl 1–2 ml or MSO4 2–4 mg IV q 1 hr) and/or paralysis (e.g., vecuronium 8–10 mg IV)	reduces elevated sympathetic tone and HTN induced by movement, tensing abdominal musculature...
drain 3–5 ml CSF if IVC present	reduces intracranial volume
hyperventilate to $PaCO_2 = 30–35$ mm Hg ("blows off" CO_2)	CO_2 is a potent vasodilator. Hyperventilation → ↓ $PaCO_2$ → ↓ CBV → ↓ ICP ✖ hyperventilation also → ↓ CBF
mannitol 0.25–1 gm/kg, then 0.25 gm/kg q 6 hrs, increase dose if IC-HTN persists & serum osmol ≤ 320 (NB: skip this step if hypovolemia or hypotension)	mannitol → initially ↑ plasma volume & ↑ serum tonicity which draws fluid out of brain → ↓ intracranial volume, may also improve rheologic properties of blood. ✖ mannitol is an osmotic diuretic, and eventually → ↓ plasma volume
if there is "osmotic room" (i.e., serum osmol < 320) bolus with 10–20 ml of 23.4% hypertonic saline (HS)	some patients refractory to mannitol will respond to HS
augmented hyperventilation to ↓ $PaCO_2$ to 25–30 mm Hg	due to risk of cerebral ischemia from ↓ CBF, monitor $SjVO_2$ (p. 1045) or CBF if possible
If IC-HTN persists, consider unenhanced head CT[b] & EEG[c]. Proceed to "second tier" therapy (p. 1051)	

[a] see text for details (p. 1050). As IC-HTN subsides, carefully withdraw treatment
[b] if IC-HTN persists, and especially for a sudden unexplained rise in ICP or loss of previously controlled ICP, give strong consideration to repeating cranial CT to rule out a surgical condition, i.e., "clot" (SDH, EDH, or ICH) or hydrocephalus
[c] EEG to rule out subclinical status epilepticus, which is a rare cause of sustained IC-HTN

Acute ICP crisis

An *acute* increase in ICP in a previously controlled patient may be due to:

1. **paroxysmal sympathetic hyperactivity** (PSH) AKA paroxysmal autonomic instability with dystonia (PAID)[65] : AKA neurostorming, AKA diencephalic seizures, AKA midbrain dysregulatory syndrome… A consensus conference[66] promulgated an assessment tool for determining the likelihood of PSH (see reference for details) which among other things includes points for:
    a) temperature > 37 °C (with increasing points up to ≥ 39 °C)
    b) pulse ≥ 100 beats/min (with increasing points up to ≥ 140)
    c) respiratory rate ≥ 18 (with increasing points up to ≥ 30)
    d) systolic BP ≥ 140 (with increasing points up to ≥ 180)
    e) diaphoresis

   f) posturing
   g) episodes that are paroxysmal in nature
   h) sympathetic hyperactivity in response to normally non-noxious stimuli
   i) episodes on ≥ 3 consecutive days
2. increased CO_2 (a potent vasodilator in the brain) e.g., by mucus plugging of part of the bronchial system, pulmonary embolism
3. development of new, or exansion of existing, intracranial hemorrhage (SDH, EDH, ICH...) monitor artifact

► **Management.** Temporary measures which may be used to quickly treat an acute ICP crisis are shown in ▶ Table 62.6.

.

Table 62.6 Measures to treat an acute ICP crisis[a]

Step	Rationale
Verify basics: check airway, neck position/compression... (see general measures in ▶ Table 62.5). For resistant or sudden IC-HTN, consider STAT unenhanced head CT	
be sure patient is sedated and paralyzed (▶ Table 62.5)	(▶ Table 62.5)
drain 3–5 ml CSF if IVC present	↓ intracranial volume
mannitol[b] 1 gm/kg IV bolus or 10–20 ml of 23.4% saline	↑ plasma volume → ↑ CBF → ↓ ICP, also ↑ serum osmolality → ↓ extracellular brain water
hyperventilate with Ambu® bag (✖ do not reduce $PaCO_2 < 25$ mm Hg)	"blow off" (reduce) $PaCO_2$ → ↓ CBV → ↓ ICP. ✖ CAUTION: due to reduced CBF, use for no more than several minutes (p. 1052)
pentobarbital[c] 100 mg slow IV or thiopental 2.5 mg/kg IV over 10 minutes	sedates, ↓ ICP, treats seizures, may be neuroprotective ✖ also myocardial depressant → ↓ MAP

[a] for measures to treat ICP that is trending up over a longer period, see ▶ Table 62.5 or information below under ICP management protocol details
[b] skip this step and go to hyperventilation if hypotensive, volume depleted, or if serum osmolarity > 320 mOsm/L
[c] the availability of pentobarbital in the U.S. has been reduced, and other sedatives (p. 1056) may need to be substituted

62.4.4 ICP management protocol details

Goals of therapy

1. keep ICP ≤ 22 mm Hg (prevents "plateau waves" from compromising cerebral blood flow (CBF) and causing cerebral ischemia and/or brain death[32])
2. keep CPP ≥ 60-70 mm Hg.[5] The primary goal is to control ICP, CPP should simultaneously be supported by maintaining adequate MAP.[67] NB: exercise caution when considering aggressive measures to elevate CPP due to the risk of adult respiratory distress syndrome (ARDS)[5]

Surgical treatment

1. traumatic intracranial masses should be treated as indicated. See surgical indications for subdural (p. 1076), epidural (p. 1074) or intraparenchymal (p. 1071) hematoma or posterior fossa mass lesions (p. 1089)
2. decompressive craniectomy may be considered for IC-HTN that cannot be controlled medically
3. as a last resort, patients with severe hemorrhagic contusions ("pulped brain") showing progressive deterioration may benefit from surgical excision of portions of the contused brain tissue, especially if not eloquent brain (p. 1051). NB: even severely contused brain may contain significant viable brain tissue

General care

Major goals

1. avoid hypoxia ($pO_2 < 60$ mm Hg)
2. avoid hypotension (SBP ≤ 90 mm Hg): 67% positive-predictive value (PPV) for poor outcome (79% PPV when combined with hypoxia)[68]

Details of general treatment measures

1. prophylaxis against steroid ulcers (if steroids are used) and Cushing's (stress) ulcers (seen in severe head injury and in increased ICP, accompanied by hypergastrinemia)[69,70,71,72,73] for all patients including peds; see Prophylaxis for stress ulcers (p. 134).
   a) elevating gastric pH: titrated antacid and/or H2 antagonist (e.g., ranitidine 50 mg IV q 8 hrs) or proton pump inhibitor. See possible increased mortality as a result of increased gastric pH (p. 135)
   b) sucralfate
2. aggressive control of fever (fever is a potent stimulus to increase CBF, and may also increase plateau waves)[32]
3. arterial line for BP monitoring and frequent ABGs
4. CVP or PA line if high doses of mannitol are needed (goal: keep patient euvolemic)
5. IV fluids
   a) choice of fluids:
      - isolated head injury: IVF of choice is isotonic (e.g., NS + 20 mEq KCl/L)
      - avoid hypotonic solutions (e.g., lactated ringers) which may impair cerebral compliance[74]
   b) fluid volume:
      - provide adequate fluid resuscitation to avoid hypotension
      - normalization of intravascular fluid volume is not detrimental to ICP
      - although fluid restriction reduces the amount of mannitol needed to control ICP,[75] the concept of "running patients dry" is obsolete[76]
      - if mannitol is required, patient should be maintained at euvolemia
      - also exercise caution in restricting fluids following SAH; see Cerebral salt wasting (p. 122)
      - if injuries to other systems are present (e.g., perforated viscus), they may dictate fluid management
   c) pressors (e.g., dopamine) are preferable to IV fluid boluses in head injury

Measures to lower ICP

General measures that should be routine

1. positioning:
   a) elevate HOB 30–45° (see below)
   b) keep head midline (to prevent kinking jugular veins)
2. light sedation: codeine 30–60 mg IM q 4 hrs PRN, or lorazepam (Ativan®) 1–2 mg IV q 4–6 hrs PRN
3. avoid hypotension (SBP < 90 mm Hg): normalize intravascular volume, support with pressors if needed
4. control HTN; in ICH, aim for patient's baseline, see Initial management of ICH (p. 1619)
5. prevent hyperglycemia: (aggravates cerebral edema) usually present in head injury,[77,78] may be exacerbated by steroids
6. intubation: for GCS ≤ 8 or respiratory distress. Consider premedicating with IV lidocaine (see below) and antibiotics (p. 1003)
7. avoid hyperventilation: keep $PaCO_2$ at the low end of eucapnia (35 mm Hg)
8. prophylactic hypothermia: non-statistically significant trend suggests reduced mortality.[79] Maintain target temperature for > 48 hours

Measures to use for documented IC-HTN

First, check General measures that should be routine above. Proceed to each step if IC-HTN persists.

1. heavy sedation and/or paralysis when necessary (also assists treatment of HTN) e.g., when patient is agitated, or to blunt the elevation of ICP that occurs with certain maneuvers such as moving the patient to CT table. Caution: with heavy sedation or paralysis, the ability to follow the neurologic exam is lost (follow ICPs)
   a) for heavy sedation (intubation recommended to avoid respiratory depression → elevation of $PaCO_2 \rightarrow \uparrow$ ICP): e.g., one of the following:
      - morphine (MSO_4): ℞ 2–4 mg/hr IV drip
      - fentanyl: ℞ 1–2 ml IV q 1 hr (or 2–5 mcg/kg/hr IV drip)
      - sufentanil: ℞ 10–30 mcg test dose, then 0.05 -2 mcg/kg/hr IV drip
      - midazolam (Versed®): ℞ 2 mg test dose, then 2–4 mg/hr IV drip
      - propofol drip (p. 110): 0.5 mg/kg test dose, then 20–75 mcg/kg/min IV drip ✖ avoid high-dose propofol (do not exceed 83 mcg/kg/min)
      - "low dose" pentobarbital (adult: 100 mg IV q 4 hrs; peds: 2–5 mg/kg IV q 4 hrs)
   b) paralysis (intubation mandatory): e.g., vecuronium 8–10 mg IV q 2–3 hrs

2. CSF drainage (when IVC is being utilized to measure ICP): 3–5 ml of CSF should be drained with the drip chamber at ≤ 10 cm above EAC. Works immediately by removal of CSF (reducing intracranial volume) and possibly by allowing edema fluid to drain into ventricles[80] (latter point is controversial)
3. "osmotic therapy" when there is evidence of IC-HTN:
   a) *mannitol* (also see below) 0.25–1 gm/kg bolus (over < 20 mins) followed by 0.25 gm/kg IVP (over 20 min) q 6 hrs PRN ICP > 22. Recent literature suggests that 1.4 gm/kg initial dose is more effective. May "alternate" with:
   furosemide (Lasix®) (also see below): adult 10–20 mg IV q 6 hrs PRN ICP > 22. Peds: 1 mg/kg, 6 mg max IV q 6 hrs PRN ICP > 22
   b) keep patient euvolemic to slightly hypervolemic
   c) if IC-HTN persists and serum osmolarity is < 320 mOsm/L, increase mannitol up to 1 gm/kg, and shorten the dosing interval
   d) if ICP remains refractory to mannitol, consider hypertonic saline, either continuous 3% saline infusion or as bolus of 10–20 ml of 23.4% saline
   (D/C after ≈ 72 hours to avoid rebound edema)
   e) hold osmotic therapy if serum osmolarity is ≥ 320 mOsm/L (higher tonicity may have no advantage and risks renal dysfunction; see below) or SBP < 100
4. hyperventilation (HPV) to $PaCO_2 = 30–35$ mm Hg (for details, see below)
   a) ✖ do not use prophylactically
   b) ✖ avoid aggressive HPV ($PaCO_2 \leq 25$ mm Hg) at all times
   c) use only for
      - short periods for acute neurologic deterioration
      - or chronically for documented IC-HTN unresponsive to sedation, paralytics, CSF drainage, and osmotic therapy
   d) avoid HPV during the first 24 hrs after injury if possible
5. ✖ steroids: the routine use of glucocorticoids is not recommended for treatment of patients with head injuries (see below)

"Second tier" therapy for persistent IC-HTN

If IC-HTN remains refractory to the above measures, and especially if there is loss of previously controlled ICP, strong consideration should be given to repeating a head CT to rule out a surgical condition before proceeding with "second tier" therapies which are either effective but with significant risks (e.g., high-dose barbiturates), or are unproven in terms of benefit on outcome. Also consider an EEG to rule out subclinical status epilepticus (seizures that are not clinically evident); see treatment measures for status epilepticus (p. 512); some medications are effective for both seizures and IC-HTN, e.g., pentobarbital, propofol…

1. high dose barbiturate therapy (p. 1055): initiate if ICP remains > 20–25 mm Hg
2. hyperventilate to $PaCO_2 = 25–30$ mm Hg. Monitoring $SjVO_2$, $AVdO_2$, and/or CBF is recommended (see below)
3. hypothermia[81,82]: patients must be monitored for a drop in cardiac index, thrombocytopenia, elevated creatinine clearance, and pancreatitis. Avoid shivering which raises ICP[82]
4. decompressive surgery:
   a) decompressive craniectomy removal of portion of calvaria.[83] Controversial (may enhance cerebral edema formation[84] and enlargement of hemorrhagic contusions[85]). Craniectomy decreased ICP to < 20 mm Hg in 85%[86] regardless of pupillary response to light, timing of craniectomy, brain shift, and age. Outcomes were improved when IC-HTN responded.[18,86,87] The RESCUEicp trial[88] showed increased survival at 6 months, and it also resulted in higher rates of vegetative state. Early decompressive craniectomy may be considered in patients undergoing emergent surgery (for fracture, EDH, SDH…).[89] Flap must be at least 12 cm in diameter, and duraplasty is mandatory. Also, see Hemicraniectomy for malignant MCA territory infarction (p. 1589)
   b) removal of large areas of contused hemorrhagic brain (makes room immediately; removes region of disrupted BBB). If contused, consider temporal tip lobectomy (no more than 4–5 cm on dominant side, 6–7 cm on non-dominant) (total temporal lobectomy[90] is probably too aggressive) or frontal lobectomy. Has not shown great therapeutic promise
5. lumbar drainage: showing some promise. Watch for "cerebral sag"
6. hypertensive therapy

Adjunctive measures

1. *lidocaine*: 1.5 mg/kg IVP (watch for hypotension, reduce dose if necessary) at least one minute before endotracheal intubation or suctioning. Blunts the rise in ICP as well as tachycardia and

systemic HTN (based on patients with brain tumors undergoing intubation under light barbiturate-nitrous oxide anesthesia; extrapolation to trauma patients is unproven)[91]

2. high frequency (jet) ventilation: consider if high levels of positive end-expiratory pressure (PEEP) are required[92] (NB: patients with reduced lung compliance, e.g., pulmonary edema, transmit more of PEEP through lungs to thoracic vessels and may raise ICP). PEEP $\le$ 10 cm H_2O does not cause clinically significant increases in ICP.[93] Higher levels of PEEP > 15–20 are not recommended. Also, rapid elimination of PEEP may cause a sudden increase in circulating blood volume which may exacerbate cerebral edema and also elevate ICP

Details of some measures employed in treating increased ICP

Elevating head of bed (HOB)

Seemingly simple, but there is still some controversy. Early data obtained from dog studies indicated that keeping the HOB at 30–45° optimized the trade-off between the following two factors as the HOB is elevated: reducing ICP (by enhancing venous outflow and by promoting displacement of CSF from the intracranial compartment to the spinal compartment) and reducing the arterial pressure (and thus CPP) at the level of the carotid arteries. Some studies showed a deleterious effect from elevating the HOB and were used to justify nursing these patients with HOB flat.[2]

Recent data[94] indicate that although mean carotid pressure (MCP) is reduced, the ICP is also reduced and the CBF is unaffected by elevating the HOB to 30°. The onset of action of raising the HOB is immediate.

Prophylactic hypothermia

Practice guideline: Prophylactic hypothermia

Level III[79]: prophylactic hypothermia:

- improves the chances of having a moderate to good outcome—4–5 on the Glasgow Outcome Score; see ▶ Table 98.4—at the end of the follow-up period when target temperatures of 32–35 °C (91.4–95 °F) were used (**note**: no clear relationship was found for cooling duration or rewarming rate)
- showed a non-significant trend suggesting that it lowers *mortality* when the target temperature is maintained for > 48 hrs (**note**: the actual target temperature and rewarming rate did not influence mortality)

Hyperventilation

Intra-arterial carbon dioxide ($PaCO_2$) is the most potent cerebrovascular vasodilator, the effect of which is probably mediated by changes in pH caused by the rapid diffusion of CO_2 across the BBB.[95] Hyperventilation (HPV) lowers ICP by reducing $PaCO_2$ which causes cerebral vasoconstriction, thus reducing the cerebral (intracranial) blood volume (CBV).[96] Of concern, vasoconstriction also lowers cerebral blood flow (CBF) which could produce focal ischemia in areas with preserved cerebral autoregulation as a result of shunting.[97,98] However, ischemia does not necessarily follow as the O_2 extraction fraction (OEF) may also increase, up to a point.[99]

Practice guideline: Hyperventilation for ICP management[a]

Level I[100]: in the absence of IC-HTN, chronic prolonged hyperventilation (HPV) ($PaCO_2 \le 25$ mm Hg) should be avoided

Level II[101]: prophylactic hyperventilation ($PaCO_2 \le 25$ mm Hg) is not recommended

Level III:

- HPV may be necessary for brief periods when there is acute neurologic deterioration, or for longer periods if there is IC-HTN refractory to sedation, paralysis, CSF drainage and osmotic diuretics[100]
- HPV should be avoided ≤ 24 hrs after head injury[101]
- if HPV is used, jugular venous oxygen saturation ($SjVO_2$) (p. 1045) or $PbtO_2$ (p. 1045) should be measured to monitor brain O_2 delivery[101]

[a] See also **Practice guideline: Early/prophylactic hyperventilation** (p. 1003).

✖ Hyperventilation (HPV) is to be used in moderation only in specific situations[3] (see below). Prophylactic HPV may actually be associated with a *worse* outcome[102] (**note:** prophylactic HPV implies cases where there are no clinical signs of IC-HTN and where IC-HTN unresponsive to other measures has not been documented by ICP monitoring). When indicated, use HPV only to $PaCO_2 = 30–35$ mm Hg (see Caveats for hyperventilation below). CBF in severe head trauma patients is already about half of normal during the first 24 hrs after injury (typically < 30 cc/100 g/min during the first 8 hours, and may be < 20 during the first 4 hours in patients with the worst injuries).[103,104,105,106] In one study, the use of HPV to $PaCO_2 = 30$ mm Hg within 8–14 hrs of severe head injury did not impair global cerebral metabolism,[99] but focal changes were not studied. Hyperventilation to $PaCO_2 < 30$ mm Hg further reduces CBF, but does not consistently reduce ICP and may cause loss of cerebral autoregulation.[47] If carefully monitored, there may be occasion to use this. There are no studies showing any improvement in outcome with aggressive HPV ($PaCO_2 \leq 25$ mm Hg) which can cause diffuse cerebral ischemia.[47] A summary of the ranges of $PaCO_2$ and the recommendations is shown in ▶ Table 62.7.

Reducing $PaCO_2$ from 35 to 29 mm Hg lowers ICP 25–30% in most patients. Onset of action: ≤ 30 seconds. Peak effect at ≈ 8 mins. Duration of effect is occasionally as short as 15–20 mins. Effect may be blunted by 1 hour (based on patients with intracranial tumors), after which it is difficult to return to normocarbia without rebound elevation of ICP.[107,108] Thus, HPV must be weaned slowly.[32]

Table 62.7 Summary of recommendations for $PaCO_2$ following head trauma (see text for details)

$PaCO_2$ (mm Hg)	Description
35–40	**normocarbia.** Use routinely
30–35	**hyperventilation.** Do not use prophylactically. Use only as follows: briefly for clinical evidence of IC-HTN (neurologic deterioration) or chronically for documented IC-HTN unresponsive to other measures
25–30	**augmented hyperventilation.** A second tier treatment. Use only when other methods fail to control IC-HTN. Additional monitoring recommended to R/O cerebral ischemia
< 25	**aggressive hyperventilation.** No documented benefit. Significant potential for ischemia

Indications for hyperventilation (HPV)

1. HPV for brief periods (minutes) at the following times
   a) prior to insertion of ICP monitor: if there are clinical signs of IC-HTN (▶ Table 60.2)
   b) after insertion of a monitor: if there is a sudden increase in ICP and/or acute neurologic deterioration, HPV may be used while evaluating patient for a treatable condition (e.g., delayed intracranial hematoma)
2. HPV for longer periods: when there is documented IC-HTN unresponsive to sedation, paralytics, CSF drainage (when available), and osmotic diuretics
3. HPV may be appropriate for IC-HTN resulting primarily from hyperemia (p. 1084)

Caveats for hyperventilation

1. avoid during the first 5 days after head injury if possible (especially first 24 hrs)
2. do not use prophylactically (i.e., without appropriate indications, see above)
3. if documented IC-HTN is unresponsive to other measures, hyperventilate only to $PaCO_2 = 30–35$ mm Hg
4. if prolonged HPV to $PaCO_2$ of 25–30 mm Hg is deemed necessary, consider monitoring $SjVO_2$, $AVdO_2$, or CBF to rule out cerebral ischemia (p. 1045)
5. do not reduce $PaCO_2 < 25$ mm Hg (except for very brief periods of a few minutes)

Mannitol

Practice guideline: Mannitol in severe traumatic brain injury

Level II[109,110]: mannitol is effective for control of IC-HTN after severe TBI (**note:** current information did not allow recommendations regarding hypertonic saline to be made[110])
- intermittent boluses may be more effective than continuous infusion
- effective doses range from 0.25–1 gm/kg body weight
- avoid hypotension (SBP < 90 mm Hg) which may result from the diuretic effect of mannitol, which can lead to ↓ circulating fluid volume

Level III[109]**:**

- indications: signs of transtentorial herniation or progressive neurological deterioration not attributable to systemic pathology
- euvolemia should be maintained (hypovolemia should be avoided) by fluid replacement. An indwelling urinary catheter is essential
- serum osmolarity should be kept < 320 mOsm when there is concern about renal failure

No controlled clinical trial has been conducted to show the benefits of mannitol over placebo.[3] The exact mechanism(s) by which mannitol provides its beneficial effects is still controversial, but probably includes some combination of the following

1. lowering ICP
   a) immediate plasma expansion[111,112,113]: reduces the hematocrit and blood viscosity (improved rheology) which increases CBF and O_2 delivery. This reduces ICP within a few minutes, and is most marked in patients with CPP < 70 mm Hg
   b) osmotic effect: increased serum tonicity draws edema fluid from cerebral parenchyma. Takes 15–30 minutes until gradients are established.[111] Effect lasts 1.5–6 hrs, depending on the clinical condition[3,114,115]
2. supports the microcirculation by improving blood rheology (see above)
3. possible free radical scavenging[116]

With bolus administration, onset of ICP lowering effect occurs in 1–5 minutes; peaks at 20–60 minutes. When urgent reduction of ICP is needed, an initial dose of 1 gm/kg should be given over 30 minutes. When long-term reduction of ICP is intended, the infusion time should be lengthened to 60 minutes[117] and the dose reduced (e.g., 0.25–0.5 gm/kg q 6 hrs). A large previous dose reduces the effectiveness of subsequent doses[75]; thus it is desirable to *use the smallest effective dose* (small frequent doses may be preferable, e.g., 0.25 mg/kg q 2–3 hrs; also results in fewer peaks as mannitol "troughs" are smoothed out). Titrating to ICP (instead of dosing at regular intervals) results in less mannitol being given.[75,118] The effectiveness of mannitol may be synergistically enhanced when combined with the use of loop acting diuretics (e.g., furosemide, see below),[119] and alternating these medications has been suggested.[75]

Cautions with mannitol

1. mannitol opens the BBB, and mannitol that has crossed the BBB may draw fluid into the CNS (this may be minimized by repeated bolus administration vs. continuous infusion[112,120]) which can aggravate vasogenic cerebral edema.[121] Thus, when it is time to D/C mannitol, it should be tapered to prevent ICP rebound[117]
2. caution: corticosteroids + phenytoin + mannitol may cause hyperosmolar nonketotic state with high mortality[32]
3. excessively vigorous bolus administration may → HTN and if autoregulation is defective → increased CBF which may promote herniation rather than prevent it[122]
4. high doses of mannitol carries the risk of acute renal failure (acute tubular necrosis), especially in the following[11,123]: serum osmolarity > 320 mOsm/L, use of other potentially nephrotoxic drugs, sepsis, pre-existing renal disease
5. large doses prevents diagnosing DI by use of urinary osmols or SG (p. 126)
6. because it may further increase CBF,[124] the use of mannitol may be deleterious when IC-HTN is due to hyperemia (p. 1084)

Furosemide

The use of furosemide (Lasix®) has been advocated, but little data exists to support this.[3] Loop acting diuretics may reduce ICP[125] by reducing cerebral edema[126] (possibly by increasing serum tonicity) and may also slow the production of CSF.[127] They also act synergistically with mannitol[128] (above).

℞: 10–20 mg IV q 6 hrs, may be alternated with mannitol such that the patient receives one or the other q 3 hrs. Hold if serum osmolarity > 320 mOsm/L.

Hypertonic saline (HS)

May reduce ICP in patients refractory to mannitol,[129,130] although no improvement in outcome over mannitol has been demonstrated.[130,131] Potentially deleterious effect on stroke penumbra in animal studies. Studies[132,133] are not adequate to make recommendations regarding use.[110]

℞: Continuous infusion: 3% saline at 25–50 ml/hr may be given through a peripheral IV. Bolus: 10–20 ml of 7.5–23.4% saline must be given through a central line. HS should be discontinued after ≈ 72 hours to avoid rebound edema.[130] Hold if serum osmolarity > 320 mOsm/L.

Steroids

Practice guideline: Glucocorticoids in severe head injury

Level I[134]: the use of glucocorticoids (steroids) is not recommended for improving outcome or reducing ICP in patients with severe TBI (except in patients with known depletion of endogenous adrenal hormones[135,136]). High-dose methylprednisolone is associated with increased mortality and is contraindicated[134]

Although glucocorticoids reduce vasogenic cerebral edema (e.g., surrounding brain tumors) and may be effective in lowering ICP in pseudotumor cerebri, they have little effect on cytotoxic cerebral edema, which is the more prevalent derangement following trauma; see Cerebral edema (p. 90).

Significant side effects may occur with steroids,[137] including coagulopathies, hyperglycemia[138] with its undesirable effect on cerebral edema—see Possible deleterious side effects of steroids (p. 626)—and increased incidence of infection (due to immunosuppression). High-dose methylprednisolone is associated with increased mortality.[139]

Non-glucocorticoid steroids (e.g., 21-aminosteroids, AKA lazaroids, including tirilazad[140,141]) and the synthetic glucocorticoid triamcinolone[142] have also failed to show overall benefit.

High-dose barbiturate therapy

Practice guideline: Barbiturates in severe head injury

Level II[143]: ✖ prophylactic use of barbiturates for burst suppression EEG is not recommended

Level II[143]: high-dose barbiturates are recommended for IC-HTN refractory to maximal medical and surgical ICP-lowering therapy. Patients should be hemodynamically stable before and during treatment

Theoretical benefits of barbiturates in head injury derive from vasoconstriction in normal areas (shunting blood to ischemic brain tissue), decreased metabolic demand for O_2 ($CMRO_2$) with accompanying reduction of CBF, free radical scavenging, reduced intracellular calcium, and lysosomal stabilization.[144] There is little question that barbiturates lower ICP, even when other treatments have failed,[145] but regarding outcome, studies have shown both benefits[146,147] and lack of same.[148,149] A subgroup of patients with preserved vasoreactivity may benefit from the use of barbiturates[150]; and when reserved for use in patients who failed to respond sufficiently to other measures, barbiturates have been shown to lower ICP.[151] Patients that do respond have a lower mortality (33%) than those in whom ICP control could not be accomplished (75%).[147]

The limiting factor for therapy is usually ***hypotension*** due to barbiturate-induced reduction of sympathetic tone[152 (p 354)] (causing peripheral vasodilatation) and direct mild myocardial depression. Hypotension occurs in ≈ 50% of patients in spite of adequate blood volume and use of dopamine.[153]

NB: the ability to follow the neurologic exam is lost with high-dose barbiturates, and one must follow ICP.

"Barbiturate coma" vs. high-dose therapy: If barbiturates are given until there is burst suppression (p. 249) on EEG, this is considered true "barbiturate coma." This results in near maximal reductions in $CMRO_2$ and CBF.[3] However, most regimens should technically be called "high dose intravenous therapy" since they simply try to establish target serum barbiturate levels (e.g., 3–4 mg% for pentobarbital), even though there is poor correlation between serum level, therapeutic benefit, and systemic complications.[3]

Adjunctive measures to administration of high-dose barbiturates:

1. consider a Swan-Ganz (PA) catheter placed during the first hour of loading dose
2. high-dose barbiturates often causes paralytic ileus: therefore NG tube to suction & IV hyperalimentation are usually needed
3. continuous EEG monitor may be employed (a double "banana" EEG montage is often used to cover a wide area) and the drug is titrated to 2–5 bursts per minute (▶ Fig. 14.1)

Indications

The use of barbiturates should be reserved for situations where the ICP cannot be controlled by the previously outlined measures,[147] as there is evidence that *prophylactic* barbiturates do not favorably alter outcome, and are associated with significant side effects, mostly hypotension,[153] that can cause neurologic deterioration.

Choice of agents

A number of agents have been studied; however, there are inadequate data to recommend one drug over another. The most information is available on pentobarbital (see below). Alternative agents which have not been as well studied: thiopental (see below), phenobarbital (p. 493) & propofol (p. 1057).

Drug info: Pentobarbital (Nembutal®)

Pentobarbital has a fast onset (full effects within ≈ 15 minutes), short duration of action (3–4 hrs), and a half–life of 15–48 hrs.

The neuro exam cannot be assessed on pentobarbital. It is a myocardial suppressant, therefore watch for hypotension. GI motility is reduced or absent, some use trickle tube feeds during pentobarbital thrapy.

Protocols for pentobarbital therapy in adults

There are many protocols. A simple one from a randomized clinical trial[151]:

1. loading dose:
    a) pentobarbital 10 mg/kg IV over 30 minutes
    b) then 5 mg/kg q 1 hr × 3 doses
2. maintenance: 1 mg/kg/hr

A more elaborate protocol:

1. *loading dose*: pentobarbital 10 mg/kg/hr IV over 4 hrs as follows:
    a) *FIRST HOUR*: 2.5 mg/kg slow IVP q 15 min × 4 doses (total: 10 mg/kg in first hr), follow BP closely
    b) *next 3 hours*: 10 mg/kg/hr continuous infusion (put 2500 mg in 250 ml of appropriate IVF, run at **K** ml/hr × 3 hrs (**K** = patient's weight in kg))
2. maintenance: 1.5 mg/kg/hr infusion (put 250 mg in 250 ml IVF and run at 1.5 × **K** ml/hr)
3. check serum pentobarbital level 1 hr after loading dose completed; usually 3.5–5.0 mg%
4. check serum pentobarbital level q day thereafter
5. if level ever > 5 mg% and ICP acceptable, reduce dose
6. baseline brainstem auditory evoked response (BAER) early in treatment. May be omitted on clinical grounds. Repeat BAER if pentobarbital level ever > 6 mg%. Reduce dose if BAER deteriorates (NB: hemotympanum may interfere with BAER)
7. goal: ICP < 24 mm Hg and pentobarbital level 3–5 mg%. Consider discontinuing pentobarbital due to ineffectiveness if ICP still > 24 with adequate drug levels × 24 hrs
8. if ICP < 20 mm Hg, continue treatment × 48 hrs, then taper dose. Backtrack if ICP rises

Sample orders if continuous EEG monitoring is available:

1. pentobarb concentration: 3000/mg/600 ml NS
2. loading dose: 5–15 mg/kg over 1 hour
3. maintenance dose:
    a) 0.4–4 mg/kg/hour
    b) titrate up or down by 0.5–1 mg/kg/hour steps to maintain 2–5 bursts/minute (some use 4–12 bursts/minute)
    c) absolute maximum dose: 10 mg/kg/hr

Neuro function takes ≈ 2 days off pentobarbital to return (▶ Table 62.8). If it is desired to perform a brain death exam, the pentobarbital level needs to be ≈ ≤ 10 mcg/ml before the exam is valid.

Table 62.8 CNS effects of various pentobarbital levels[a]

Degree of CNS depression	mg%	mcg/ml
level for valid brain death exam	≤ 1	≤ 10
sedated, relaxed, easily aroused	0.05–0.3	0.5–3
heavy sedation, difficult to arouse, respiratory depression	2	20
"coma" level (burst suppression occurs in most patients)	5	50

[a] levels reported are for intolerant patients; there is significant variability between patients, and tolerant patients may not be sedated even at levels as high as 100 mcg/ml

Drug info: Thiopental (Pentothal®)

May be useful when a rapidly acting barbiturate is needed (e.g., intra-op) or when large doses of pentobarbital are not available. One of many protocols is as follows (note: thiopental has not been as well studied for this indication, but is theoretically similar to pentobarbital[154,155]):

1. loading dose: thiopental 5 mg/kg (range: 3–5) IV over 10 minutes → transient burst suppression (< 10 minutes) and blood thiopental levels of 10–30 mcg/ml. Higher doses (≈ 35 mg/kg) have been used in the absence of hypothermia to produce longer duration burst suppression for cardiopulmonary bypass
2. follow with continuous infusion of 5 mg/kg/hr (range: 3–5) for 24 hours
3. may need to rebolus with 2.5 mg/kg as needed for ICP control
4. after 24 hours, fat stores become saturated, reduce infusion to 2.5 mg/kg/hr
5. titrate to control ICP or use EEG to monitor for electrocerebral silence
6. "therapeutic" serum level: 6–8.5 mg/dl

Drug info: Propofol (Diprivan®)

Level II[143]: propofol may control ICP after several hours of dosing, but it does not improve mortality or 6 month outcome. ✖ Caution: high-dose propofol (total dose > 100 mg/kg for > 48 hrs) can cause significant morbidity (see propofol infusion syndrome).

℞: 0.5 mg/kg test dose, then 20–75 mcg/kg/min infusion. Increase by 5–10 mcg/kg/min q 5–10 minutes PRN ICP control (do not exceed 83 mcg/kg/min = 5 mg/kg/hr).

Side effects: include propofol infusion syndrome (p. 140). Use with caution at doses > 5 mg/kg/hr or at any dose for > 48 hrs.

63 Skull Fractures

63.1 Types of skull fractures

Classified as either closed (simple fracture) or open (compound fracture).

Diastatic fractures extend into and separate sutures. More common in young children.[1]

63.2 Linear skull fractures over the convexity

90% of pediatric skull fractures are linear and involve the calvaria.

▶ Table 63.1 shows some differentiating features to distinguish linear skull fractures from vessel grooves and skull suture lines.

By themselves, linear skull fractures over the convexity rarely require surgical intervention.

Table 63.1 Differentiating linear skull fractures from normal *plain* film findings

Feature	Linear skull fracture	Vessel groove	Suture line
density	dark black	gray	gray
course	straight	curving	follows course of known suture lines
branching	usually none	often branching	joins other suture lines
width	very thin	thicker than fracture	jagged, wide

63.3 Depressed skull fractures

For special considerations in pediatrics, see Depressed skull fractures (p. 1101) in pediatrics section.

63.3.1 Indications for surgery

See **Practice guideline: Surgical management of depressed skull fractures** (p. 1062). Some additional observations regarding surgery to elevate a depressed skull fracture in an adult:

1. consider surgery for depressed skull fractures with deficit referable to underlying brain
2. ✖ more conservative treatment is recommended for fractures overlying a major dural venous sinus (**note:** exception: depressed fractures overlying and depressing one of the dural sinuses may be dangerous to elevate, and if the patient is neurologically intact, and no indication for operation (e.g., CSF leak mandates surgery) may be best managed conservatively).

Practice guideline: Surgical management of depressed skull fractures

Indications for surgery

Level III[2]:

1. open (compound) fractures
   a) surgery for fractures depressed > thickness of calvaria and those not meeting criteria for nonsurgical management listed below
   b) nonsurgical management may be considered if
      - there is no evidence (clinical or CT) of dural penetration (CSF leak, intradural pneumocephalus on CT…)
      - and no significant intracranial hematoma
      - and depression is < 1 cm
      - and no frontal sinus involvement
      - and no wound infection or gross contamination
      - and no gross cosmetic deformity
2. closed (simple) depressed fractures: may be managed surgically or nonsurgically

Timing of surgery
Level III[2]: early surgery to reduce risk of infection

Surgical methods
Level III[2]:

1. elevation and debridement are recommended
2. option: if there is no evidence of wound infection, primary bone replacement
3. antibiotics should be used for all compound depressed fractures

There is no evidence that elevating a depressed skull fracture will reduce the subsequent development of posttraumatic seizures,[3] which are probably more related to the initial brain injury.

63.3.2 Surgical treatment for depressed skull fractures

General information

Booking the case: Craniotomy: for depressed skull fracture

Also see defaults & disclaimers (p. 25).

1. position: (depends on location of the fracture)
2. post-op: ICU
3. blood: type & screen (for severe fractures: type and cross 2 U PRBC)
4. consent (in lay terms for the patient—not all-inclusive):
   a) procedure: surgery in the area of the skull fracture to bone fragments that may have been displaced, to repair the covering of the brain, to remove any foreign material that can be identified and any permanently damaged brain tissue (i.e., dead brain tissue), remove any blood clot and stop any bleeding identified, possible placement of intracranial pressure monitor. If a large opening has to be left in the skull, it may require surgery to correct in a number of months (3 or more)
   b) alternatives: nonsurgical management
   c) complications: usual craniotomy complications (p. 25), plus any permanent brain injury that has already occurred is not likely to recover, seizures may occur (with or without the surgery), hydrocephalus, infection (including delayed infection/abscess)

Technical considerations of surgery

Surgical goals
See reference,[4] modified.

1. debridement of skin edges
2. elevation of bone fragments
3. repair of dural laceration
4. debridement of devitalized brain
5. reconstruction of the skull
6. skin closure

Techniques

1. with open (compound) contaminated fractures, it may be necessary to excise depressed bone. In these cases or when air sinuses are involved, to minimize the risk of infecting the flap, some surgeons follow the patient for 6–12 months to rule out infection before performing a cosmetic cranioplasty. There has been no documented increase in infection with replacement of bone fragments; soaking the fragments in povidone-iodine has been recommended[4]
2. elevating the bone may be facilitated by drilling burr holes around the periphery and either using rongeurs or craniotome to excise the depressed portion
3. in cases where laceration of a major dural sinus is suspected and surgery is mandated, adequate preparation must be made for dural sinus repair[5]; NB: the SSS is often to the right of the sagittal suture (p. 61)
   a) prepare for massive blood loss

  b) have small Fogarty catheter ready to temporarily occlude sinus
  c) have dural shunt ready (Kapp-Gielchinsky shunt, if available, has an inflatable balloon at both ends)
  d) prep out saphenous vein area for vein graft
  e) bone fragments that may have lacerated sinus should be removed last

63.4 Basal skull fractures

63.4.1 General information

Most basal (AKA basilar) skull fractures (BSF) are extensions of fractures through the cranial vault.

Severe basilar skull fractures may produce shearing injuries to the pituitary gland.

BSF, especially those involving the clivus, may be associated with traumatic aneurysms. This rarely occurs in pediatrics.[6]

63.4.2 Some specific basal skull fracture types

Temporal bone fractures

General information

The major concerns with temporal bone fractures are: hearing loss, facial nerve injury and CSF leak. Temporal bone fractures were traditionally categorized into two basic types (or a mixture of the two) (this system originated with cadaveric studies[7]):

- **longitudinal fracture**: more common (70–90%). Usually results from a lateral blow to the head.[8] Typically passes through the petro-squamosal suture, parallel to and through EAC. Often but not always passing anterior to the inner ear structures and also sparing the VII and VIII nerves. It may cause a conductive hearing loss by disrupting the ossicular chain and and/or by producing hemotympanum. Can often be diagnosed on otoscopic inspection of the EAC
- **transverse fracture**: perpendicular to EAC. Commonly associated with a blow to the back of the head.[8] Extends from the jugular foramen through the petrous pyramid to the foramen spinosum and foramen lacerum, often passing through the cochlea and may place stretch on the geniculate ganglion, resulting in deficits of the VIII nerve and VII, respectively, with sensorineural hearing loss in 50%[8]

► **Alternative classification.** The traditional classification above correlates poorly with clinically relevant issues of hearing loss, facial nerve injury and CSF leak.[9] It is now favored to classify temporal bone fractures based on CT scan assessment of involvement of the **otic capsule** (containing the cochlea, vestibule and semicircular canals (SCC))[10]:

- **otic-capsule sparing** (OCS)
- **otic-capsule violating** (OCV)

Posttraumatic facial palsy

General information

Posttraumatic unilateral peripheral facial nerve palsy occurs in 15-20% of longitudinal petrous bone fractures, and in 50% of transverse fractures.[8]

Management of posttraumatic facial palsy

Management is often complicated by multiplicity of injuries (including head injury requiring endotracheal intubation) making it difficult to determine the time of onset of facial palsy. Guidelines:

1. regardless of time of onset:
   a) steroids (glucocorticoids) are often utilized (efficacy unproven[8])
   b) consultation with ENT physician is usually indicated
2. immediate onset of unilateral peripheral facial palsy (i.e., within a few hours of injury): facial EMG (AKA electroneuronography[11] or ENOG) takes at least 72 hrs to become abnormal (∴ generally performed no earlier than 2-3 days, and no later than 2-3 weeks).[8] These cases are often followed and are possible candidates for surgical VII nerve decompression if no improvement occurs with steroids (timing of surgery is controversial, but is usually not done emergently)
3. delayed onset of unilateral peripheral facial palsy (may be days to weeks): follow serial ENOGs, if continued nerve deterioration occurs while on steroids, and activity on ENOG drops to less than 10% of the contralateral side, surgical decompression may be considered (controversial, thought to improve recovery from ≈ 40% to ≈ 75% of cases)

Posttraumatic hearing loss

Can be conductive or sensorineural (see above). See section 61.3 for causes of posttraumatic hearing loss other than temporal bone fractures.

Clival fractures

See reference.[12]

3 categories (75% are longitudinal or transverse):

1. longitudinal: may be associated with injuries of vertebrobasilar vessels, including:
   a) dissection or occlusion: may cause brainstem infarction
   b) traumatic aneurysms
2. transverse: may be associated with injuries to the anterior circulation
3. oblique

Clival fractures are highly lethal. May be associated with:

1. cranial nerve deficits: especially III through VI; bitemporal hemianopsia
2. CSF leak
3. diabetes insipidus
4. delayed development of traumatic aneurysms[13]

Occipital condyle fractures

These are considered in the section on Spine fractures (p. 1156).

63.4.3 Radiographic diagnosis

BSF appear as linear lucencies through the skull base.

CT scan with multiplanar projections is the most sensitive means for directly demonstrating BSF.

Plain skull X-rays and clinical criteria (see below) may also be able to make the diagnosis.

Indirect radiographic findings (on CT or plain films) that suggest BSF include: pneumocephalus (diagnostic of BSF in the absence of an open fracture of the cranial vault), air/fluid level within or opacification of air sinus with fluid (suggestive).

63.4.4 Clinical diagnosis

Some of these signs may take several hours to develop. Signs include:

1. CSF otorrhea or rhinorrhea
2. hemotympanum or laceration of external auditory canal
3. postauricular ecchymoses (Battle's sign)
4. periorbital ecchymoses (raccoon's eyes) in the absence of direct orbital trauma, especially if bilateral
5. cranial nerve injury:
   a) VII and/or VIII: usually associated with temporal bone fracture
   b) olfactory nerve (Cr. N. I) injury: often occurs with anterior fossa BSF and results in anosmia, this fracture may extend to the optic canal and cause injury to the optic nerve (Cr. N. II)
   c) VI injury: can occur with fractures through the clivus (see below)

63.4.5 Management

NG tubes

✖ Caution: cases have been reported with BSF where an NG tube has been passed intracranially through the fracture[14,15,16] and is associated with fatal outcome in 64% of cases. Possible mechanisms include: a cribriform plate that is thin (congenitally or due to chronic sinusitis) or fractured (due to a frontal basal skull fracture or a comminuted fracture through the skull base).

Suggested contraindications to blind placement of an NG tube include: trauma with possible basal skull fracture, ongoing or history of previous CSF rhinorrhea, meningitis with chronic sinusitis.

Prophylactic antibiotics/vaccination

The routine use of prophylactic antibiotics is controversial. This remains true even in the presence of a CSF fistula; see CSF fistula (cranial) (p. 415). However, most ENT physicians recommend treating fractures through the nasal sinuses as open contaminated fractures, and they use broad spectrum antibiotics (e.g., ciprofloxacin) for 7–10 days.

If there is a CSF leak, **pneumococcal vaccine** is recommended for most patients (p. 341).

Treatment of the BSF

Most do not require treatment by themselves. However, conditions that may be associated with BSF that may require specific management include:

1. "traumatic aneurysms" (p. 1491) [17]
2. posttraumatic carotid-cavernous fistula (p. 1519)
3. CSF fistula: operative treatment may be required for persistent CSF rhinorrhea; see CSF fistula (cranial) (p. 415)
4. meningitis or cerebral abscess: may occur with BSF into air sinuses (frontal or mastoid) even in the absence of an identifiable CSF leak. May even occur many years after the BSF was sustained; see Post craniospinal trauma meningitis / posttraumatic meningitis (p. 340)
5. cosmetic deformities
6. posttraumatic facial palsy (see below)

63.5 Craniofacial fractures

63.5.1 Frontal sinus fractures

General information

Frontal sinus fractures account for 5–15% of facial fractures.

In the presence of a frontal sinus fracture, intracranial air (pneumocephalus) on CT, even without a clinically evident CSF leak, must be presumed to be due to dural laceration (although it could also be due to a basal skull fracture, below).

Anesthesia of the forehead may occur due to supratrochlear and/or supraorbital nerve involvement.

The risks of posterior wall fractures are not immediate, but may be delayed (some even by months or years) and include:

1. brain abscess
2. CSF leak with risk of meningitis
3. cyst or mucocele formation: injured frontal sinus mucosa has a higher predilection for mucocele formation than other sinuses.[18] Mucoceles may also develop as a result of frontonasal duct obstruction due to fracture or chronic inflammation. Mucoceles are prone to infection (mucopyocele), which can erode bone and expose dura with risk of infection

Anatomic considerations of the frontal sinus

The frontal sinus begins to appear around age 2 yrs, and becomes radiographically visible by age 8 as it extends above the superior orbital rim.[19] The sinus is lined with respiratory epithelium, the mucous secretion of which drains through the frontonasal duct medially and inferiorly into the middle nasal meatus.

Surgical considerations

Indications

Linear fractures of the anterior wall of the frontal sinus are treated expectantly.

Indications for exploration of posterior wall fractures are *controversial.*[20] Some argue that a few mm of displacement, or that CSF fistula that resolves may not require exploration. Others vehemently disagree.

Technique

In the presence of a traumatic forehead laceration, the frontal sinus may be exposed through judicious incorporation of the laceration in a forehead incision. Without such a laceration, either a bicoronal (souttar) skin incision or a butterfly incision (through the lower part of the eyebrows, crossing the midline near the glabella) is used.

In the presence of pneumocephalus, if no obvious dural laceration is found, the dural undersurface of the frontal lobes should be checked for leaks. Extradural inspection and repair is rarely indicated; the act of lifting the dura off the floor of the frontal fossa in the region of the ethmoid sinuses often creates lacerations.[21] Intradural repair is accomplished using a graft (fascia lata is most desirable; periosteum is thinner but is often acceptable) which is held in place with sutures and must extend all the way back to the ridge of the sphenoid wing (fibrin glue may be a helpful adjunct).

A periosteal flap is placed across the floor of the frontal fossa to help isolate the dura from the frontal sinus and to prevent CSF fistula.

Dealing with frontal sinus

✖ Simple packing of the sinus (with bone wax, Gelfoam®, muscle, or fat) increases the possibility of infection or mucocele formation.

The rear wall of the sinus is removed (so-called cranialization of the frontal sinus). The sinus is then exenterated (mucosa is stripped from sinus wall down to the nasofrontal duct, the mucosa is inverted over itself in the region of the duct and is packed down into the duct, and temporalis muscle plugs are then packed into the frontonasal ducts[20]), and the bony wall of the sinus is drilled with a diamond burr to remove tiny remnants of mucosa found in the surface of bone that may proliferate and form a mucocele.[18] If there is any remnant of sinus, it may then be packed with abdominal fat that fills all corners of the cavity. Post-op risks related to frontal sinus injury include: infection, mucocele formation, and CSF leak.

63.5.2 Le Fort fractures

Complex fractures through inherently weak "cleavage planes" resulting in an unstable segment ("floating face"). Shown in ▶ Fig. 63.1 (usually occur as variants of this basic scheme).

- Le Fort I: *transverse* AKA transmaxillary fracture. Fracture line crosses pterygoid plate and maxilla just above the apices of the upper teeth. May enter maxillary sinus(es)
- Le Fort II: *pyramidal*. Fracture extends upward across inferior orbital rim and orbital floor to medial orbital wall, then across nasofrontal suture. Often from downward blow to the nasal area
- Le Fort III: *craniofacial dislocation*. Involves zygomatic arches, zygomaticofrontal suture, nasofrontal suture, pterygoid plates, and orbital floors (separating maxilla from cranium). Requires significant force, and is therefore often associated with other injuries, including brain injuries

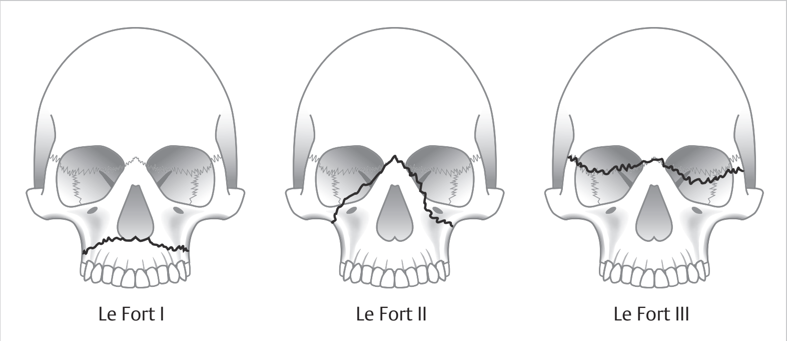

Fig. 63.1 Le Fort fractures.

63.6 Pneumocephalus

63.6.1 General information

AKA (intra)cranial aerocele, AKA pneumatocele, is defined as the presence of intracranial gas. It is critical to distinguish this from tension pneumocephalus which is gas under pressure (see below). The gas may be located in any of the following compartments: epidural, subdural, subarachnoid, intraparenchymal, intraventricular.

63.6.2 Etiologies of pneumocephalus

Anything that can cause a CSF leak can produce associated pneumocephalus (p. 418).

1. skull defects
   a) post neurosurgical procedure
      - craniotomy: risk is higher when patient is operated with surgery in the sitting position[22]
      - shunt insertion[23,24]
      - burr hole drainage of chronic subdural hematoma[25,26]: incidence is probably < 2.5%[26] although higher rates have been reported
   b) posttraumatic
      - fracture through air sinus (frontal, ethmoid…): including basal skull fracture
      - open fracture over convexity (usually with dural laceration)
   c) congenital skull defects: including defect in tegmen tympani[27]
   d) neoplasm (osteoma,[28] epidermoid,[29] pituitary tumor): usually caused by tumor erosion through floor of sella into sphenoid sinus
2. infection
   a) with gas-producing organisms
   b) mastoiditis
3. post invasive procedure:
   a) lumbar puncture
   b) ventriculostomy
   c) spinal anesthesia[30]
4. spinal trauma (LP could be included here as well)
5. barotrauma[31]: e.g., with scuba diving (possibly through a defect in the tegmen tympani)
6. may be potentiated by a CSF drainage device in the presence of a CSF leak[32]

63.6.3 Presentation

H/A in 38%, N/V, seizures, dizziness, and obtundation.[33] An intracranial succussion splash is a rare (occurring in ≈ 7%) but pathognomonic finding. Tension pneumocephalus may additionally cause signs and symptoms just as any mass (may cause focal deficit or increased ICP).

63.6.4 Differential diagnosis (things that can mimic pneumocephalus)

Although intracranial low-density on CT may occur with epidermoid, lipoma, or CSF, nothing is as intensely black as air. This is often better appreciated on bone-windows than on soft-tissue windows and the Hounsfield units (p. 238) should be close to -1000.

63.6.5 Tension pneumocephalus

Intracranial gas can develop elevated pressure in the following settings:

1. when nitrous oxide anesthesia is not discontinued prior to closure of the dura[34]; see nitrous oxide, N_2O (p. 109)
2. when a "ball-valve" effect occurs due to an opening to the intracranial compartment with soft tissue (e.g., brain) that may permit air to enter but prevent exit of air or CSF
3. when trapped room temperature air expands with warming to body temperature: a modest increase of only ≈ 4% results from this effect[35]
4. in the presence of continued production by gas-producing organisms

63.6.6 Diagnosis

Pneumocephalus is most easily diagnosed on CT,[36] which can detect quantities of air as low as 0.5 ml. Air appears dark black (darker than CSF) and has a Hounsfield coefficient of –1000. One characteristic finding with bilateral pneumocephalus is the Mt. Fuji sign in which the two frontal poles appear peaked and are surrounded by and separated by air, resembling the silhouette of the twin peaks of Mt. Fuji[26] (see ▶ Fig. 63.2). Intracranial gas may also be evident on plain skull X-rays.

Since simple pneumocephalus usually does not require treatment, it is critical to differentiate it from tension pneumocephalus, which may need to be evacuated if symptomatic. It may be quite difficult to distinguish the two; brain that has been compressed e.g., by a chronic subdural hematoma may not expand immediately post-op and the "gas gap" may mimic the appearance of gas under pressure.

63.6.7 Treatment

When pneumocephalus is due to gas-producing organisms, treatment of the primary infection is initiated and the pneumocephalus is usually followed.

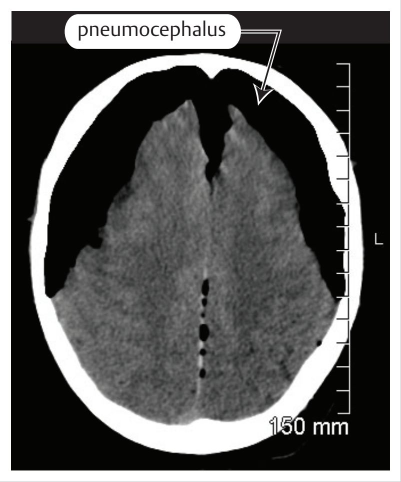

Fig. 63.2 Mt. Fuji sign with bilateral pneumocephalus. Image: axial noncontrast CT scan.

Treatment of non-infectious simple pneumocephalus depends on whether or not the presence of a CSF leak is suspected. If there is no leak the gas will be resorbed with time, and if the mass effect is not severe it may simply be followed. If a CSF leak is suspected, management is as with any CSF fistula; see CSF fistula (cranial) (p. 415).

Treatment of significant or symptomatic post-op pneumocephalus by breathing 100% O_2 via a nonrebreather mask increases the rate of resorption[37] (100% FiO_2 can be tolerated for 24–48 hours without serious pulmonary toxicity[38]).

Tension pneumocephalus producing significant symptoms must be evacuated. The urgency is similar to that of an intracranial hematoma. Dramatic and rapid improvement may occur with the release of gas under pressure. Options include placement of new twist drill or burr holes, or insertion of a spinal needle through a pre-existing burr hole (e.g., following a craniotomy).

64 Traumatic Hemorrhagic Conditions

64.1 Posttraumatic parenchymal injuries

64.1.1 Cerebral edema

Surgical decompression is occasionally an option; see **Practice guideline: Posttraumatic cerebral edema** (p. 1071).

Practice guideline: Posttraumatic cerebral edema

Indications and timing for surgery

Level III[1]: bifrontal decompressive craniectomy within 48 hrs of injury is a treatment option for patients with diffuse, medically refractory posttraumatic cerebral edema and associated IC-HTN

64.1.2 Diffuse injuries

Patients with severe diffuse injuries occasionally may be considered for decompressive craniectomy; see **Practice guideline: Diffuse injuries** (p. 1071).

Practice guideline: Diffuse injuries

Indications for surgery

Level III[1]: decompressive craniectomy is an option for patients with refractory IC-HTN and diffuse parenchymal injury with clinical and radiographic evidence for impending transtentorial herniation

64.2 Hemorrhagic contusion

64.2.1 General information

AKA traumatic intracerebral hemorrhage (TICH). The definition is not uniformly agreed upon. Often considered as high density areas on CT (some exclude areas < 1 cm diameter[2]). TICH usually produce much less mass effect than their apparent size. Most commonly occur in areas where sudden deceleration of the head causes the brain to impact on bony prominences (e.g., temporal, frontal, and occipital poles) in coup or contrecoup fashion.

TICH often enlarge and/or coalesce with time as seen on serial CTs. They also may appear in a delayed fashion (see below). Surrounding low density may represent associated cerebral edema. CT scans months later often show surprisingly minimal or no encephalomalacia.

64.2.2 Treatment

Practice guideline: Surgical management of TICH

- Level III[1]: Indications for surgical evacuation for TICH:
  - progressive neurological deterioration referable to the TICH, medically refractory IC-HTN, or signs of mass effect on CT
  - or TICH volume > 50 cm^3 cc or ml
  - or GCS = 6–8 with frontal or temporal TICH volume > 20 cm^3 with midline shift (MLS) ≥ 5 mm (p. 1110) and/or compressed basal cisterns on CT (p. 1109)
- nonoperative management with intensive monitoring and serial imaging: may be used for TICH without neurologic compromise and no significant mass effect on CT and controlled ICP

64.2.3 Delayed traumatic intracerebral hemorrhage (DTICH)

TICH demonstrated in patients on imaging that was not evident on initial admitting CT scan.

Incidence of DTICH in patients with GCS ≤ 8: ≈ 10%[3,4] (reported incidence varies with resolution of CT scanner,[5] timing of scan, and definition). Most DTICH occur within 72 hrs of the trauma.[4] Some patients seem to be doing well and then present with an apoplectic event (although DTICH accounted only for 12% of patients who “talk and deteriorate”[6]).

Factors that contribute to formation of DTICH include local or systemic coagulopathy, hemorrhage into an area of necrotic brain softening, and coalescence of extravasated microhematomas.[7]

Treatment is the same as for TICH (see above).

Outcome for patients with DTICH described in the literature is generally poor, with a mortality ranging from 50–75%.[7]

64.3 Epidural hematoma

64.3.1 General information

Incidence of epidural hematoma (EDH): 1% of head trauma admissions (which is ≈ 50% the incidence of acute subdurals). Ratio of male:female = 4:1. Usually occurs in young adults, and is rare before age 2 yrs or after age 60 (perhaps because the dura is more adherent to the inner table in these groups).

Dogma was classically that a skull fracture disrupts the anterior branch of the middle meningeal artery as it exits its canal in the temporal bone to enter the skull, causing arterial bleeding that gradually dissects the dura from the inner table resulting in a delayed deterioration. Alternate hypothesis: dissection of the dura from the inner table occurs first, followed by bleeding into the space thus created.

Source of bleeding: 85% = arterial bleeding (the middle meningeal artery is the most common source of middle fossa EDHs). Many of the remainder of cases are due to bleeding from middle meningeal vein or dural sinus.

70% occur laterally over the hemispheres with their epicenter at the pterion, the rest occur in the frontal, occipital, and posterior fossa (5–10% each).

64.3.2 Presentation with EDH

“Textbook” presentation (< 10%-27% have this classic presentation[8]):

- brief posttraumatic loss of consciousness (LOC): from initial impact
- followed by a “lucid interval” for several hours
- then, obtundation, contralateral hemiparesis and ipsilateral pupillary dilatation as a result of mass effect from hematoma

Deterioration usually occurs over a few hours, but may take days and rarely, weeks (the longer intervals may be associated with venous bleeding).

Other presenting findings: H/A, vomiting, seizure (may be unilateral), hemi-hyperreflexia + unilateral Babinski sign, and elevated CSF pressure (LP is seldom used any longer). Bradycardia is usually a late finding. In peds, EDH should be suspected if there is a 10% drop in hematocrit after admission.

Contralateral hemiparesis is not uniformly seen, especially with EDH in locations other than laterally over the hemisphere. Shift of the brainstem away from the mass may produce compression of the opposite cerebral peduncle on tentorial notch which can produce *ipsilateral* hemiparesis (so called Kernohan’s phenomenon or Kernohan’s notch phenomenon),[9] a false localizing sign.

60% of patients with EDH have a dilated pupil, 85% of which are *ipsilateral*.

No initial loss of consciousness occurs in 60%. No lucid interval in 20%. NB: a lucid interval is not pahtognomonic for EDH and may also be seen in other conditions (including subdural hematoma).

64.3.3 Differential diagnosis

- subdural hematoma (see below for differentiating radiographic features)
- a posttraumatic disorder described by Denny-Brown consisting of a posttraumatic “lucid interval” followed by bradycardia, brief periods of restlessness and vomiting, without intracranial hypertension or mass. Children especially may have H/A, and may become drowsy and confused. Theory: a form of vagal syncope. CT must be done to rule out EDH

64.3.4 Evaluation

Plain skull X-rays

Usually not helpful. No fracture is identified in 40% of EDH. In these cases the patient's age was almost always < 30 yrs.

CT scan in EDH

"Classic" CT appearance occurs in 84% of cases: high density biconvex (lenticular) shape adjacent to the skull (▶ Fig. 64.1). In 11% the side against the skull is convex and that along the brain is straight, and in 5% it is crescent shaped (resembling subdural hematoma).[10] EDH may cross dural barriers (viz. falx or tentorium) (▶ Fig. 64.2) distinct from SDH, which is limited to one side, however EDH are usually limited by skull sutures which SDH are not. EDH usually has uniform density, sharply defined edges on multiple cuts, high attenuation (undiluted blood), is contiguous with inner table, and is

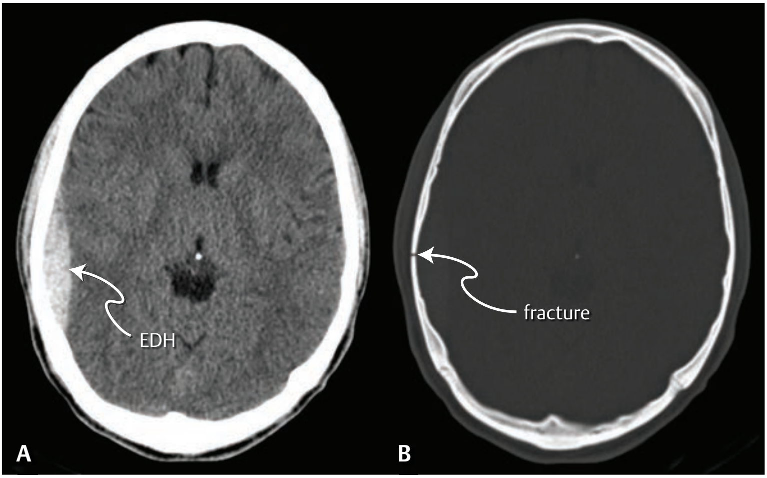

Fig. 64.1 Epidural hematoma, right side.
Epidural hematoma (EDH) appears as biconvex (lenticular) shaped hyperdensity adjacent to inner table of skull. Note the underlying skull fracture seen on bone windows.
Image: axial CT scan. A: brain window. B: bone window.

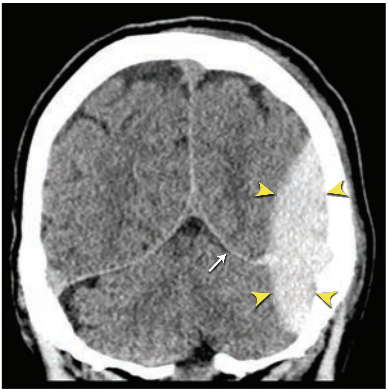

Fig. 64.2 Epidural hematoma, left side.
Image: coronal CT illustrating an EDH (*yellow arrowheads*) crossing the tentorium (*white arrow*), which in addition to its biconvex shape, helps distinguish this from a subdural hematoma (SDH).

usually confined to small segment of calvaria. Mass effect is frequent. Occasionally, an epidural may be isodense with brain and may not show up unless IV contrast is given,[10] although other clues are often present (e.g., inward displacement of the cortical ribbon). Mottled density may occur, and in some cases is associated with a hyperacute EDH.[11]

64.3.5 Treatment of EDH

General management

Prepare for surgery if indications below are met. Prompt surgery if signs of local mass effect, signs of herniation (increasing drowsiness, pupil changes, hemiparesis…) or cardiorespiratory abnormalities.

Management includes: admit to ICU with q 1 hour neuro checks, NPO. Reverse coagulopathies.

Medical

CT may detect small EDHs and can be used to follow them. However, in most cases, EDH is a surgical condition (see below).

Nonsurgical management may be attempted in patients not meeting surgical indications below, which generally limited to:

1. small (≤ 1 cm maximal thickness) subacute or chronic EDH[12]
2. minimal neurological signs/symptoms (e.g., slight lethargy, mild H/A) without focal deficit and without evidence of herniation
3. ✖ although medical management of p-fossa EDHs has been reported, these are more dangerous (see below) due to small volume of p-fossa and vulnerability of brainstem to compression by even modest hematoma expansion. Surgery is recommended

Optional: for persistent headache a short course of steroids (1-3 days) may help, then taper.

Follow-up CT: early after admission (e.g., 6 hours) and then any time the patient becomes symptomatic, or in 1-2 wks if clinically stable. Repeat in 1–3 mos (to document resolution).

In 50% of cases there will be a slight transient increase in size between days 5–16, and some patients required emergency craniotomy when signs of herniation occurred.[13]

Surgical

Surgical indications and timing

See also Practice guideline (p. 1074). EDH in pediatric patients is riskier than adults since there is less room for clot. The threshold for surgery in pediatrics should be very low.

Practice guideline: Surgical management of EDH

Indications for surgery

Level III[14]:

1. EDH volume* > 30 cm^3 should be evacuated regardless of GCS.
2. EDH with all of the following characteristics can be managed nonsurgically with serial CT scans and close neurological observation in a neurosurgical center:
    a) volume* < 30 cm^3
    b) and thickness < 15 mm
    c) and midline shift (MLS) < 5 mm (p. 1110)
    d) and GCS > 8
    e) and no focal neurologic deficit

*The estimated volume of a lens = $(1.6 \text{ to } 2) \times r^2t = (0.4 \text{ to } 0.5) \times d^2t \approx (H \times AP \times T)/2$ (that is 1/2 the products of the height times the length in the AP dimension times the thickness T).

Helpful benchmarks: for the volume of a 1.5 cm thick EDH to be < 30 cc it would have to have a diameter (not radius) < 6.3–7 cm. For a 1 cm thick EDH to be < 30 cc, it would have to have a diameter < 7.7–8.6 cm.

Timing of surgery

Level III[14]: it is strongly recommended that patients with an acute EDH and GCS < 9 and anisocoria undergo surgical evacuation ASAP

Booking the case: Craniotomy for acute EDH/SDH

Also see defaults & disclaimers (p. 25).

1. position: (depends on location of bleed, usually supine)
2. blood: type & screen (for severe SDH: T & C 2 U PRBC)
3. post-op: ICU
4. consent (in lay terms for the patient—not all-inclusive):
   a) procedure: surgery through the skull to remove blood clot, stop any bleeding identified, possible placement of intracranial pressure monitor
   b) alternatives: nonsurgical management
   c) complications: usual craniotomy complications (p. 25) plus further bleeding which may cause problems (especially in patients taking blood thinners, antiplatelet drugs including aspirin, or those with coagulation abnormalities or previous bleeds) and may require further surgery, any permanent brain injury that has already occurred is not likely to recover, hydrocephalus

Surgical technical issues

Evacuation is performed in the OR unless the patient herniates in E/R and access to OR is not within acceptable timeframe (see Exploratory burr holes (p. 1014)). Objectives:

1. clot removal: lowers ICP and eliminates focal mass effect. Blood is usually thick coagulum, thus exposure must large enough provide access to most of clot. Craniotomy permits more complete evacuation of hematoma than e.g., burr holes[14]
2. hemostasis: attempt to locate and neutralize the source of the hematoma (e.g., middle meningeal artery), coagulate bleeding soft tissue (dural veins & arteries). Requires an exposure larger than e.g., burr holes
3. prevent reaccumulation: some bleeding or oozing typically occurs post op, and the dura is now detached from inner table facilitates recurrence of EDH. Strategies to prevent:
   a) apply bone wax to intra-diploic bleeders
   b) dural tack-up sutures: small sutures (e.g., 4-0 braided nylon) from the dura to small drill holes in the bone along the edges of the craniotomy and a central "tenting" suture through drill holes in the flap
   c) perforating the bone flap with a drill and placing a subgaleal drain which is maintained for several days or until output is scant

64.3.6 Mortality with EDH

Overall: 20–55% (higher rates in older series). Optimal diagnosis and treatment within a few hours results in 5–10% estimated mortality (12% in a recent CT era series[15]). Mortality in patients without lucid interval is double that for patients with a lucid interval. Bilateral Babinski's or decerebration pre-op → worse prognosis. Death is usually due to respiratory arrest from uncal herniation causing injury to the midbrain.

20% of patients with EDH on CT also have ASDH at autopsy or operation. Mortality with both lesions concurrently is higher, reported range: 25–90%.

64.3.7 Special cases of epidural hematoma

Delayed epidural hematoma (DEDH)

Definition: an EDH that is not present on the initial CT scan, but is found on subsequent CT. Comprise 9–10% of all EDHs in several series.[16,17]

Theoretical risk factors for DEDH include the following (NB: many of these risk factors may be incurred *after* the patient is admitted following a negative initial CT):

1. lowering ICP either medically (e.g., osmotic diuretics) and/or surgically (e.g., evacuating contralateral hematoma) which reduces tamponading effect
2. rapidly correcting shock (hemodynamic "surge") may cause DEDH[18]
3. coagulopathies

DEDH tend to occur in patients with severe head injury and associated systemic injuries. However, DEDH have also been infrequently reported in *mild* head injury (GCS > 12) .[19] Presence of a skull fracture has been identified as a common feature of DEDH.[19]

Key to diagnosis: high index of suspicion. Avoid a false sense of security imparted by an initial "nonsurgical" CT. 6 of 7 patients in one series improved or remained unchanged neurologically despite enlarging EDH (most eventually deteriorate). 1 of 5 with an ICP monitor did not have a heralding increase in ICP. May develop once an intracranial lesion is surgically treated, as occurred in 5 of 7 patients within 24 hrs of evacuation of another EDH. 6 of 7 patients had known skull fractures in the region where the delayed EDH developed,[17] but none of 3 had a skull fracture in another report.[18]

Posterior fossa epidural hematoma

Comprise ≈ 5% of EDH.[20,21] More common in 1st two decades of life. Although as many as 84% have occipital skull fractures, only ≈ 3% of children with occipital skull fractures develop p-fossa EDH. The source of bleeding is usually not found, but there is a high incidence of tears of the dural sinuses. Cerebellar signs are surprisingly lacking or subtle in most. See surgical indications (p. 1090). Overall mortality is ≈ 26% (mortality was higher in patients with an associated intracranial lesion).

64.4 Acute subdural hematoma

64.4.1 General information

The magnitude of impact damage (p. 1000), as opposed to secondary damage, is usually much higher in acute subdural hematoma (ASDH) than in epidural hematomas, which generally makes this lesion much more lethal. There is often associated underlying brain injury, which may be less common with EDH. Symptoms may be due to compression of the underlying brain with midline shift, in addition to parenchymal brain injury and possibly cerebral edema.[22,23]

Two common causes of traumatic ASDH:

1. accumulation around parenchymal laceration (usually frontal or temporal lobe). There is usually severe underlying primary brain injury. Often no "lucid interval." Focal signs usually occur later and are less prominent than with EDH
2. surface or bridging vessel torn from cerebral acceleration-deceleration during violent head motion. With this etiology, primary brain damage may be less severe, a lucid interval may occur with later rapid deterioration

ASDH may also occur in patients receiving anticoagulation therapy,[24,25] usually with, but sometimes without, a history of trauma (the trauma may be minor). Receiving anticoagulation therapy increases the risk of ASDH 7-fold in males and 26-fold in females.[24]

64.4.2 CT scan in ASDH

Acute subdurals are usually hyperdense compared to brain (posible exceptions: patients with low hematocrit, SDH that admix with CSF as they form). Edema in the adjacent brain may be present.

Locations of ASDH:

- convexity (the most common). Usually appears as a crescentic mass of increased density adjacent to inner table (► Fig. 64.3), compared to a convexity epidural hematoma which is usually biconvex (► Fig. 64.1).
- interhemispheric (p. 1079) (► Fig. 64.6)
- layering on the tentorium (tentorial subdural, ► Fig. 64.4)
- in p-fossa (p. 1089)

► **Differences in convexity EDH from SDH.** SDH is typically more diffuse, less uniform, usually *crescentic* over brain surface, often less dense (possibly from mixing with CSF). SDH cannot cross intradural barriers such as the falx and tentorium, whereas an EDH can.

► **SDH changes with time on CT.** The density of subdural hematomas on CT scans changes with time as blood breaks down and transforms from thick coagulum to low viscosity fluid (see

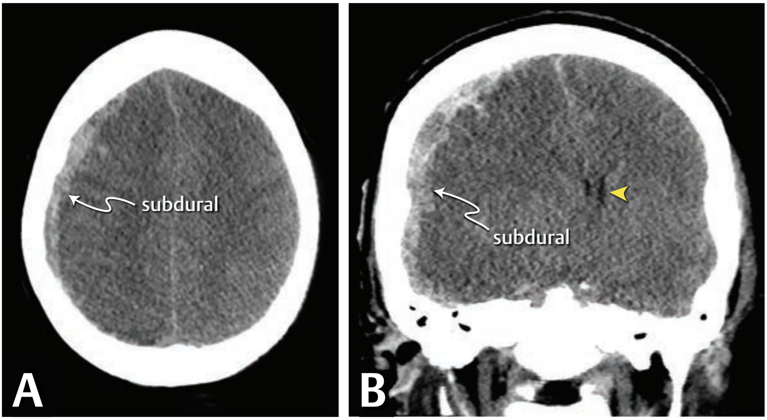

Fig. 64.3 Acute (convexity) subdural hematoma, right side.
Note the characteristic high-density crescentic shape of the hematoma. The lateral ventricles (*yellow arrowhead*) have been shifted to the patient's left.
Image: noncontrast CT scan, brain window. A: axial, B: coronal.

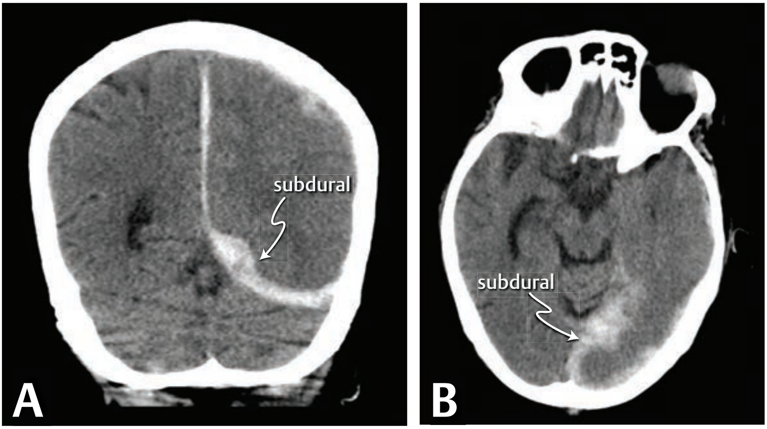

Fig. 64.4 Tentorial subdural hematoma, left side.
Image: noncontrast CT scan in the same patient, brain window. A: coronal, B: axial.

▶ Table 64.1 and ▶ Fig. 64.5, times are approximate, and vary from patient to patient). Acute SDH are usually hyperdense to brain, and become isodense after ≈ 2 wks where the only clues may be apparent obliteration of sulci or inward displacement of cortical surface from inner table of skull and lateralizing shift (the latter may be absent if the SDH are bilateral). Subsequently, the SDH becomes hypodense to brain and is considered a chronic subdural hematoma (p. 1081). Membrane formation begins by about 4 days after injury.[26]

Table 64.1 ASDH density changes on CT with time

Category	Time frame	Density on CT relative to brain
acute	1 to 3 days	hyperdense
subacute	4 days to 2 or 3 wks	≈ isodense
chronic	usually > 3 wks and < 3–4 mos	hypodense (approaching density of CSF)
	after about 1–2 months	may become lenticular shaped (similar to epidural hematoma) with density > CSF, < fresh blood

64.4.3 Treatment

Indications for surgery

Level III surgical indications are shown in **Practice guideline: Surgical management of ASDH** (p. 1078). Other factors that should be considered:

1. presence of anticoagulants or platelet inhibitors: patients in good neurologic condition may be better served by reversing these agents prior to operating (to increase the safety of surgery)
2. location of hematoma: in general, an SDH high over the convexity is less threatening than a temporal/parietal SDH of the same volume that also has MLS
3. patient's baseline level of function, DNR status…
4. while the guidelines suggest evacuating SDH < 10 mm thick in some circumstances, clots that are smaller than this may not be causing problems but may simply be an epiphenomenon

Practice guideline: Surgical management of ASDH

Indications for surgery

Level III[27]:

1. ASDH with thickness > 10 mm or midline shift (MLS) > 5 mm (on CT) should be evacuated regardless of GCS
2. ASDH with thickness < 10 mm and MLS < 5 mm (see text regarding the evacuation of ASDH < 10 mm thick) should undergo surgical evacuation if:
   a) GCS drops by ≥ 2 points from injury to admission
   b) and/or the pupils are asymmetric or fixed and dilated
   c) and/or ICP is > 20 mm Hg
3. monitor ICP in all patients with ASDH and GCS < 9

Timing of surgery

Level III[27]: ASDH meeting surgical criteria should be evacuated ASAP (for issues regarding timing of surgery, see text)

Surgical methods

Level III[27]: ASDH meeting the above criteria for surgery should be evacuated via craniotomy with or without bone flap removal and duraplasty (a large craniotomy flap is often required to evacuate the thick coagulum and to gain access to possible bleeding sites).

Timing of surgery

Timing of surgery for ASDH is a matter of controversy. As a general principle, when surgery for ASDH is indicated it should be done as soon as possible.

"Four hour rule"

This "rule" was based on a 1981 series of 82 patients with ASDH,[28] which held that:

1. patients operated within 4 hrs of injury had 30% mortality, compared to 90% mortality if surgery was delayed > 4 hrs
2. functional survival (Glasgow Outcome Scale ≥ 4, see ▶ Table 98.4) rate of 65% could be achieved with surgery within 4 hrs
3. other factors related to outcome in this series included:

a) post-op ICP: 79% of patients with functional recovery had post-op ICPs that didn't exceed 20 mm Hg, whereas only 30% of patients who died had ICP < 20 mm Hg
b) initial neuro exam
c) age was *not* a factor in this study (ASDH tend to occur in older patients than EDH)

However, a subsequent study of 101 patients with ASDH found a delay to surgery (delays > 4 hours from the injury) showed a nonstatistically-significant trend where mortality increased from 59% to 69% and functional survival decreased (Glasgow Outcome Scale ≤ 4, see ▶ Table 98.4) from 26% to 16%.[29]

Booking the case: Acute subdural hematoma

Same as for acute epidural hematoma (p. 1075).

Technical considerations

One may start with a small linear dural opening to effect clot removal and enlarge it as needed and only if brain swelling seems controllable. The actual bleeding site is often not identified at the time of surgery.

64.4.4 Morbidity and mortality with ASDH

Mortality range: 50–90% (a significant percentage of this mortality is from the underlying brain injury, and not the ASDH itself).

Mortality is traditionally thought to be higher in aged patients (60%), and is 90–100% in patients on anticoagulants.[25]

In a series of 101 patients with ASDH, functional recovery was 19%.[29] Postoperative seizures occurred in 9%, and did not correlate with outcome. The following variables were identified as strongly influencing outcome:

- mechanism of injury: the worst outcome was with motorcycle accidents, with 100% mortality in unhelmeted patients, 33% in helmeted
- age: correlated with outcome only > 65 yrs of age, with 82% mortality and 5% functional survival in this group (other series had similar results[30])
- neurologic condition on admission: the ratio of mortality to functional survival rate related to the admission Glasgow Coma Scale (**GCS**) is shown in ▶ Table 64.2
- postoperative ICP: patients with peak ICPs < 20 mm Hg had 40% mortality, and no patient with ICP > 45 had a functional survival

Of all the above factors, only the time to surgery and postoperative ICP can be directly influenced by the treating neurosurgeon.

Table 64.2 Outcome as related to admission GCS

Admission GCS	Mortality	Functional survival
3	90%	5%
4	76%	10%
5	62%	18%
6 & 7	51%	44%

64.4.5 Special cases of acute subdural hematoma

Interhemispheric subdural hematoma

General information

Subdural hematoma along the falx between the two cerebral hemispheres (older term: interhemispheric scissure) (▶ Fig. 64.6).

May occur in children,[31] possibly associated with child abuse.[32]

In adults, may be the consequence of[33]:

- head trauma in 79–91%

- ruptured aneurysm[34] in ≈ 12%
- surgery in the vicinity of the corpus callosum
- spontaneously: rare, mostly with the use of anticoagulation

Incidence is unknown. Spontaneous cases should be investigated for possible underlying aneurysm. Occasionally may be bilateral, sometimes may be delayed (see below)

Most often are asymptomatic, or may present with the so-called "falx syndrome"—paresis or focal seizures contralateral to the hematoma. Other presentations: gait ataxia, dementia, language disturbance, oculomotor palsies.

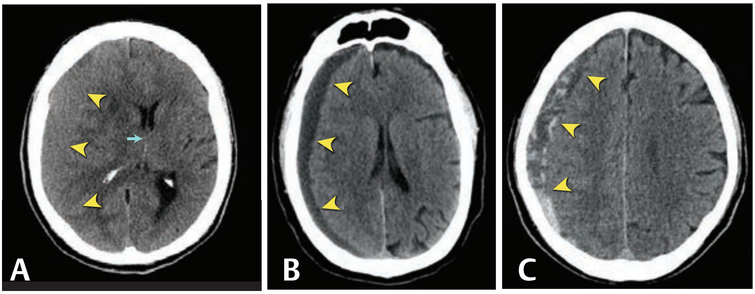

Fig. 64.5 Changes in subdural hematomas over time.
Right-sided convexity subdural hematomas (*yellow arrowheads*) in 3 different patients.
Image: axial CT scans. A: subacute subdural (isodense to brain and can barely be seen. Note absence of sulci on the ipsilateral side and the right-to-left midline shift (blue arrow) are clues to its presence), B: chronic SDH (low density), C: this subdural is often read as "acute on chronic SDH" (note the higher density areas mixed with lower density).

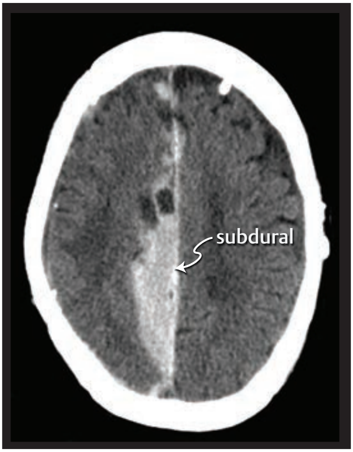

Fig. 64.6 Interhemispheric subdural hematoma on the right side of the falx in a 76-year-old male on anticoagulants.
Image: axial noncontrast CT scan.

Treatment

Controversial. Small asymptomatic cases may be managed expectantly. Surgery should be considered for progressive neurological deterioration with larger lesions. Approached through a parasagittal craniotomy. ✖ Surgery for these lesions can be treacherous—there is risk of venous infarction and one often finds they are dealing with a superior sagittal sinus injury.

Outcome

Reported mortality: 25–42%. Mortality is higher in the presence of altered levels of consciousness. Mortality rate may actually be lower (24%) than with all-comers.[33] This is significantly lower than SDH in other sites (see above).

Delayed acute subdural hematoma (DASDH)

DASDHs have received less attention than delayed epidural or intraparenchymal hematomas. Incidence is ≈ 0.5% of operatively treated ASDHs.[7]

Definition: ASDH not present on an initial CT (or MRI) that shows up on a subsequent study. Indications for treatment are the same as for ASDH. Neurologically stable patients with a small DASDH and medically controllable ICP are managed expectantly.

Infantile acute subdural hematoma

General information

Infantile acute subdural hematoma (IASDH) is often considered a special case of SDH. Roughly defined as an acute SDH in an infant due to minor head trauma without initial loss of consciousness or cerebral contusion,[35] possibly due to rupture of a bridging vein. The most common trauma is a fall backwards from sitting or standing. The infants will often cry immediately and then (usually within minutes to 1 hour) develop a generalized seizure. Patients are usually < 2 yrs old (most are 6–12 mos, the age when they first begin to pull themselves up or walk).[36]

These clots are rarely pure blood, and are often mixed with fluid. 75% are bilateral or have contralateral subdural fluid collections. It is speculated that IASDH may represent acute bleeding into a preexisting fluid collection.[36]

Skull fractures are rare. In one series, retinal and preretinal hemorrhages were seen in all 26 patients.[35]

Treatment

Treatment is guided by clinical condition and size of hematoma. Minimally symptomatic cases (vomiting, irritability, no altered level of consciousness and no motor disturbance) with liquefied hematoma may be treated with percutaneous subdural tap, which may be repeated several times as needed. Chronically persistent cases may require a subduroperitoneal shunt.

More symptomatic cases with high density clot on CT require craniotomy. A subdural membrane similar to those seen in adult chronic SDH is not unusual.[36] *Caution*: these patients are at risk of developing intraoperative hypovolemic shock.

Outcome

8% morbidity and mortality rate in one series.[35] Much better prognosis than ASDH of all ages probably because of the absence of cerebral contusion in IASDH.

64.5 Chronic subdural hematoma

64.5.1 General information

Originally termed “pachymeningitis hemorrhagica interna” by Virchow[37] in 1857. Chronic subdural hematomas (CSDH) generally occur in the elderly, with an average age of ≈ 63 yrs; exception: subdural collections of infancy (p. 1087). Head trauma is identified in < 50% (sometimes rather trivial trauma can produce these lesions). Other risk factors: alcohol abuse, seizures, CSF shunts, coagulopathies (including therapeutic anticoagulation[25]), and patients at risk for falls (e.g., with hemiplegia from previous stroke). CSDHs are bilateral in ≈ 20–25% of cases.[38,39]

Hematoma thickness tends to be larger in older patients due to a decrease in brain weight and increase in subdural space with age.[40]

Classically CSDHs contain dark “motor oil” fluid which does not clot.[41] When the subdural fluid is clear (CSF), the collection is termed a subdural hygroma (p. 1085).

64.5.2 Pathophysiology

Many CSDHs probably start out as acute subdurals. Blood within the subdural space evokes an inflammatory response. Within days, fibroblasts invade the clot and form neomembranes on the inner (cortical) and outer (dural) surface. This is followed by ingrowth of neocapillaries, enzymatic fibrinolysis, and liquefaction of bpslood clot. Fibrin degradation products are reincorporated into new clots and inhibit hemostasis. The course of CSDH is determined by the balance of plasma effusion and/or rebleeding from the neomembranes on the one hand and reabsorption of fluid on the other.[42,43]

64.5.3 Presentation

Patients may present with minor symptoms of headache, confusion, language difficulties (e.g., word-finding difficulties or speech arrest, usually with dominant hemisphere lesions), or TIA-like symptoms (p. 1685). Or, they may develop varying degrees of coma, hemiplegia, or seizures (focal, or less often generalized). Often, the diagnosis may be unexpected prior to imaging.

The Markwalder scale (▶ Table 64.3[44] is similar to other scales used for grading neurologic status of patients with CSDH, and is sometimes used for research purposes.

Table 64.3 Markwalder neurologic grading scale for CSDH[44]

Grade	Neurologic condition
0	• neurologically normal
1	• alert & oriented • mild symptoms (e.g., H/A) • no neurologic deficit or minimal neurologic deficit (e.g., reflex asymmetry)
2	• drowsy or disoriented • variable neurologic deficit (e.g., hemiparesis)
3	• stuporous but responds appropriately to noxious stimulus • severe focal signs (e.g., hemiplegia)
4	• comatose • no motor response to noxious stimulus • decerebrate or decorticate posturing

64.5.4 Imaging

Chronic subdurals most often appear on CT as hypodense crescentic extra-axial collections (see ▶ Fig. 64.5 panel B).

64.5.5 Treatment

Management overview

1. seizure prophylaxis: used by some. It may be safe to discontinue after a week or so if there are no seizures. If a late seizure occurs with or without prior use of ASMs, longer-term therapy is required
2. coagulopathies (including anticoagulation & antiplatelet therapy) should be reversed
3. treatment of the hematoma
   a) indications:
      - symptomatic lesions (usually > 1 cm maximal thickness). Symptoms include: focal deficit, mental status changes, seizures, severe H/A…
      - or progressive increase in size on serial imaging (CT or MRI scans)
   b) treatment options:
      - surgical evacuation of the hematoma: numerous methods employed (see below)
      - endovascular embolization of the middle meningeal artery (p. 1935)

Surgical options

Despite the fact that CSDH is one of the most common neurosurgical conditions, there is no consensus regarding optimal treatment. For details of techniques (burr holes, use of subdural drain…) see below.

1. placing two burr holes, and irrigating through and through with tepid saline until the fluid runs clear
2. single "large" burr hole with irrigation and aspiration: see below
3. single burr hole drainage with placement of a subdural drain, maintained for 24–48 hrs (removed when output becomes negligible)
4. twist drill craniostomy: see below (note that small "twist drill" drainage *without* subdural drain has higher recurrence rate than e.g., burr holes)

5. craniotomy with excision of subdural membrane (may be necessary in cases which persistently recur after above procedures, possibly due to seepage from the subdural membrane). Still a safe and valid technique.[45] *No* attempt should be made to remove the deep membrane adherent to the surface of brain

Techniques that promote continued drainage after the immediate procedure and that may thus reduce residual fluid and prevent reaccumulation:
1. use of a subdural drain: (see below)
2. using a generous burr hole under the temporalis muscle: (see below)
3. bed-rest restriction with the head of the bed flat (1 pillow is permitted) with mild overhydration for 24–48 hours post-op (or if a drain is used, until 24–48 hours after it is removed). May promote expansion of the brain and expulsion of residual subdural fluid. Allowing patients to sit up to 30–40° immediately post-op was associated with higher radiographic recurrence rate (2.3% for those kept flat, vs. 19% for those who sat up) but usually did not require reoperation[46]
4. some advocate continuous lumbar subarachnoid infusion when the brain fails to expand; however, there are possible complications[47]

Booking the case: Craniotomy: for chronic subdural hematoma

Also see defaults & disclaimers (p. 25).
1. position: (usually supine), horseshoe headrest
2. post-op: ICU
3. consent (in lay terms for the patient—not all-inclusive):
    a) procedure: surgery through the skull to remove blood clot, stop any bleeding identified, place a drainage tube to allow further fluid to drain after surgery for a day or so
    b) alternatives: nonsurgical management
    c) complications: usual craniotomy complications (p. 25) plus further bleeding which may cause problems (especially in patients taking blood thinners, antiplatelet drugs including aspirin, or those with coagulation abnormalities or previous bleeds) and may require further surgery, hydrocephalus

Twist drill craniostomy for chronic subdurals

This method is thought to decompress the brain more slowly and avoids the presumed rapid pressure shifts that occur following other methods, which may be associated with complications such as intraparenchymal (intracerebral) hemorrhage. May even be performed at the bedside under local anesthesia. There was no difference in outcome compared to burr holes.[48]

A 0.5 cm incision is made in the scalp in the rostral portion of the hematoma, and then a twist drill hole is placed at a 45° angle to the skull, aimed in the direction of the longitudinal axis of the collection. If the drill does not penetrate the dura, this is done with an 18 Ga spinal needle. A ventricular catheter is inserted into the subdural space, and is drained to a standard ventriculostomy drainage bag maintained 20 cm *below* the level of the craniostomy site[49,50,51] (below). The patient is kept flat in bed (see above). Serial CTs assess the adequacy of drainage. The catheter is removed when at least ≈ 20% of the collection is drained and when the patient shows signs of improvement, which occurs within a range of 1–7 days (mean of 2.1 days). Some include a low pressure shunt valve in the system to prevent reflux of fluid or air.

Burr holes for chronic subdural hematomas

To prevent recurrence, the use of *small* burr holes (without a subdural drain) is not recommended. A generous (> 2.5 cm in diameter—it is recommended that one actually measure this) subtemporal craniectomy should be performed, and bipolar coagulation is used to shrink the edges of the dura and subdural membrane back to the full width of the bony opening (do not try to separate these two layers as this may promote bleeding). This allows continued drainage of fluid into the temporalis muscle where it may be resorbed. A piece of Gelfoam® may be placed over the opening to help prevent fresh blood from oozing into the opening.

Subdural drain

Use of a subdural drain is associated with a decrease in need for repeat surgery from 19% to 10%.[48,52] If a subdural drain is used, a closed drainage system is recommended. Difficulties may occur with ventriculostomy catheters because the holes are small and are restricted to the tip region (so-designed to keep choroid plexus from plugging the catheter when inserted into the ventricles when used as intended as a CSF shunt), especially with thick "oily" fluid (on the positive side, slow drainage may be desirable). The drainage bag is maintained ≈ 50–80 cm below the level of the head.[44,51] An alternative is a small Jackson-Pratt® drain using "thumb-print" indentation of the suction bulb, which provides good drainage with a self-contained one-way valve (however, there may be a risk of excessive negative pressure with overcompression of the bulb). Drainage for 48 hours was as effective as 96 hours.[48]

Post-op, the patient is kept flat (see above). Prophylactic antibiotics may be given until ≈ 24–48 hrs following removal of the drain, at which time the HOB is gradually elevated. CT scan prior to removal of the drain (or shortly after removal) may be helpful to establish a baseline for later comparison in the event of deterioration.

There is a case report of administration of urokinase through a subdural drain to treat reaccumulation of clot following evacuation.[53]

64.5.6 Outcome

General information

There is clinical improvement when the subdural pressure is reduced to close to zero, which usually occurs after ≈ 20% of the collection is removed.[51]

Patients who have high subdural fluid pressure tend to have more rapid brain expansion and clinical improvement than patients with low pressures.[44]

Residual subdural fluid collections after treatment are common, but clinical improvement does not require complete resolution of the fluid collection on CT. CTs showed persistent fluid in 78% of cases on post-op day 10, and in 15% after 40 days,[44] and may take up to 6 months for complete resolution. Recommendation: do *not* treat persistent fluid collections evident on CT (especially before ≈ 20 days post-op) unless it increases in size on CT or if the patient shows no recovery or deteriorates.

76% of 114 patients were successfully treated with a single drainage procedure using a twist drill craniostomy with subdural ventricular catheter, and 90% with one or two procedures.[49] These statistics are slightly better than twist drill craniostomy with aspiration alone (i.e., no drain).

Complications of surgical treatment

Although these collections often appear innocuous, severe complications may occur, including:

1. seizures (including intractable status epilepticus)
2. intracerebral hemorrhage (ICH): occurs in 0.7–5%.[54] Very devastating in this setting: one–third of these patients die and one third are severely disabled (also, see below)
3. failure of the brain to re-expand and/or reaccumulation of the subdural fluid
4. tension pneumocephalus
5. subdural empyema: may also occur with untreated subdurals[55]

In 60% of patients ≥ age 75 yrs (and in no patients < 75 yrs), rapid decompression is associated with hyperemia in the cortex immediately beneath the hematoma, which may be related to the complications of ICH or seizures.[54] All complications are more common in elderly or debilitated patients.

Overall mortality with surgical treatment for CSDH is 0–8%.[54] In a series of 104 patients treated mostly with craniostomy,[56] mortality was ≈ 4%, all of which occurred in patients > 60 yrs old and were due to accompanying disease. Another large personal series reported 0.5% mortality.[57] Worsening of neurologic status following drainage occurs in ≈ 4%.[56]

64.6 Spontaneous subdural hematoma

64.6.1 General information

Occasionally patients with no identifiable trauma will present with severe H/A with or without associated findings (nausea, seizures, lethargy, focal findings including possible ipsilateral hemiparesis[58]…) and CT or MRI discloses a subdural hematoma that may be acute, subacute or chronic in appearance. The onset of symptoms is often sudden.[58]

64.6.2 Risk factors

Risk factors identified in a review of 21 cases in the literature[59] include:

1. hypertension: present in 7 cases
2. vascular abnormalities: arteriovenous malformation (AVM), aneurysm[60]
3. neoplasm
4. infection: including meningitis, tuberculosis
5. substance abuse: alcoholism, cocaine[61]
6. hypovitaminosis: especially vitamin C deficiency[37]
7. coagulopathies, including:
   a) iatrogenic (anticoagulation e.g., with warfarin)
   b) Ginkgo biloba (GB) extract: EGb761 and LI1379. Contains ginkgolides (especially Type B), which are inhibitors of platelet activating factor (PAF) at high concentrations[62]; also cause vasodilation and decreased blood viscosity. There have been case reports showing temporal relationship of hemorrhage to intake of GB,[63] especially at higher doses over long periods of time. However, no consistent alteration was demonstrable in 29 measurable coagulation/clotting variables after 7 days[64] (bleeding time was mildly prolonged in some case reports[63,65]). Some individuals may possibly be more susceptible to the supplement, and there may be as-yet uncharacterized interactions with other entities (such as alcohol, aspirin…), but studies so far have been unrevealing[66]
   c) factor XIII deficiency (protransglutaminase).[67,68] In peds: history may include report of bleeding from umbilical cord at birth. Check factor XIII levels as coagulation parameters may be normal or only slightly elevated
8. seemingly innocuous insults (e.g., bending over) or injuries resulting in no direct trauma to the head (e.g., whiplash injuries)
9. intracranial hypotension: spontaneous (p. 421), or following epidural anesthesia, lumbar puncture, or VP shunt[69,70]

64.6.3 Etiology

The bleeding site was determined in 14 of the 21 cases, and was *arterial* in each, typically involving a cortical branch of the MCA in the area of the Sylvian fissure[59] where there is a large number of branches to a wide cortical area.

Possible mechanisms for arterial rupture in idiopathic acute subdural hematoma (ASDH) include tears occurring secondary to sudden head movements or trivial head trauma of the following[71,72]:

1. small artery at perpendicular branch point off a cortical artery
2. small artery connecting the dura and cortex
3. adhesions between cortical artery and dura

64.6.4 Treatment

Same as for traumatic SDH. If symptomatic and/or > ≈ 1 cm thick, surgical evacuation is the treatment of choice. For subacute to chronic subdurals, burr hole evacuation is usually adequate (see above). For acute SDH, a craniotomy is usually required, and should expose the Sylvian fissure to identify bleeding point(s). Microsurgical repair of arterial wall has been described.[72]

64.7 Traumatic subdural hygroma

64.7.1 General information

From the Greek hygros, meaning wet. AKA traumatic subdural effusion, AKA hydroma. Excess fluid in the subdural space (may be clear, blood tinged, or xanthochromic and under variable pressure) is almost always associated with head trauma, especially alcohol-related falls or assaults.[73] Skull fractures were found in 39% of cases. Distinct from chronic subdural hematoma, which is usually associated with underlying cerebral contusion, and usually contains darker clots or brownish fluid ("motor oil" fluid), and may show membrane formation adjacent to inner surface of dura (hygromas lack membranes).

"Simple hygroma" refers to a hygroma without significant accompanying conditions. "Complex hygroma" refers to hygromas with associated significant subdural hematoma, epidural hematoma, or intracerebral hemorrhage.

64.7.2 Pathogenesis

Mechanism of formation of hygroma is probably a tear in the arachnoid membrane with resultant CSF leakage into the subdural compartment. Hygroma fluid contains pre-albumin, which is also found in CSF but not in subdural hematomas. The most likely locations of arachnoid tears are in the Sylvian fissure or the chiasmatic cistern. Another possible mechanism is post-meningitis effusion (especially influenza meningitis).

May be under high pressure. May increase in size (possibly due to a flap-valve mechanism) and exert mass effect, with the possibility of significant morbidity. Cerebral atrophy was present in 19% of patients with simple hygromas.

64.7.3 Presentation

▶ Table 64.4 shows clinical findings of subdural hygromas. Many present without focal findings. Complex hygromas usually present more acutely and require more urgent treatment.

Table 64.4 Major clinical features of traumatic subdural hygromas[73]

Type of hygroma	Simple	Complex	Total
number of patients	66	14	80
spontaneous eye opening	74%	57%	71%
disorientation or stupor	65%	57%	64%
mental status change without focal signs	52%	50%	51%
neurological plateau with deficit or delayed deterioration	42%	7%	36%
seizures (usually generalized)	36%	43%	38%
hemiparesis	32%	21%	30%
neck stiffness	26%	14%	24%
anisocoria (maintained light reflex)	15%	7%	14%
headache	14%	14%	14%
alert (no mental status change)	8%	0%	6%
hemiplegia	6%	14%	8%
comatose (responsive to pain only)	3%	43%	10%

64.7.4 Imaging

On CT, the density of the fluid is similar to that of CSF (▶ Fig. 64.7 panel A).

Signal characteristics on MRI follow those of CSF.

▶ **Differentiating a hygroma from a chronic subdural hematoma on imaging.** This may be very difficult. Clues:

1. the fluid in hygromas should be almost identical to CSF on CT (chronic SDH will tend to be slightly higher density) and MRI
2. **"cortical vein sign"** : hygromas typically expand the subarachnoid space and it may be possible to see a vein bridging from the cortex (which has been displaced inward) to the arachnoid membrane (which is now pressed up against the inner table of the skull) (▶ Fig. 64.7). In contrast, SDH will generally compress the arachnoid membrane against the brain and there will not be bridging veins. This sign is infrequently observed, and is best demonstrated on some MRI sequences or CT angiogram

64.7.5 Treatment

Asymptomatic hygromas do not require treatment. Recurrence following simple burr hole drainage is common. Many surgeons maintain a subdural drain for 24–48 hrs post-op. Recurrent cases may require either a craniotomy to locate the site of CSF leak (may be very difficult), or a subdural-peritoneal shunt may be placed.

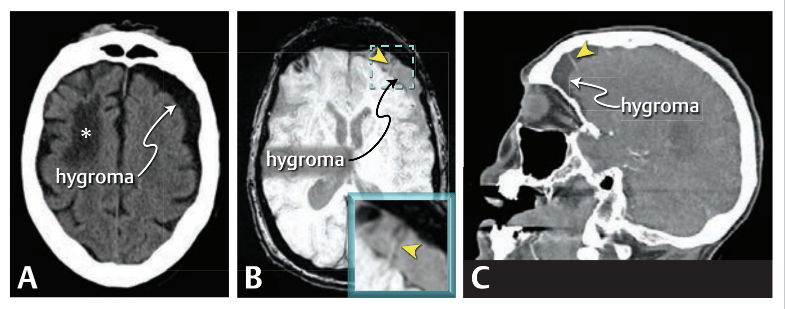

Fig. 64.7 Subdural hygroma over the left convexity.
Image: A: Axial CT scan (note previous stroke on the right (*asterisk*)), B: MRI SWI axial (inset shows magnified detail of area indicated by *broken blue line*), C: CTA sagittal.
Note: the "cortical vein sign" (bridging cortical vein) (*yellow arrowhead* in B & C, not seen in A).

64.7.6 Outcome

Outcome may be more related to accompanying injuries than to the hygroma itself.

5 of 9 patients with complex hygromas and subdural hematoma died. For simple hygromas, morbidity was 20% (12% for decreased mental status without focal findings, 32% if hemiparesis/plegia was present).

64.8 Extraaxial fluid collections in children

64.8.1 Differential diagnosis

1. benign subdural collection in infants (see below)
2. chronic *symptomatic* extraaxial fluid collections or effusions (see below)
3. cerebral atrophy: should not contain xanthochromic fluid with elevated protein
4. "external hydrocephalus": ventricles often enlarged, fluid is CSF (p. 433)
5. normal variant of enlarged subarachnoid spaces and interhemispheric fissure
6. acute subdural hematoma: high density (fresh blood) on CT (occasionally these will appear as low density collections in children with low hematocrits). Will usually be unilateral (the others above are usually bilateral). These lesions may occur as birth injuries, and typically present with seizures, pallor, tense fontanelle, poor respirations, hypotension, and retinal hemorrhages
7. "craniocerebral disproportion" (head too large for the brain)[74]: extracerebral spaces enlarged up to 1.5 cm in thickness and filled with CSF-like fluid (possibly CSF), ventricles at upper limits of normal, deep sulci, widened interhemispheric fissure, normal intracranial pressure. Patients are developmentally normal. May be the same as benign extra-axial fluid of infancy (see below). Making this diagnosis with certainty is difficult in first few months of life

64.8.2 Benign subdural collections of infancy

General information

Benign subdural collections (or effusions) of infancy,[75,76] are perhaps better characterized by the term benign extra-axial fluid collections of infancy, since it is difficult to distinguish whether they are subdural or subarachnoid.[77] They appear on CT as peripheral hypodensities over the frontal lobes in infants. Imaging may also show dilatation of the interhemispheric fissure, cortical sulci,[78] and Sylvian fissure. Ventricles are usually normal or slightly enlarged, with no evidence of transependymal absorption. Brain size is normal. Transillumination is increased over both frontal regions. The fluid is usually clear yellow (xanthochromic) with high protein content. The etiology of these is unclear; some cases may be due to perinatal trauma. They are more common in term infants than preemies. Must be differentiated from external hydrocephalus (p. 433).

Presentation

Mean age of presentation is ≈ 4 months.[77]

May show: signs of elevated intracranial pressure (tense or large fontanelle, accelerated head growth crossing percentile curves), developmental delay usually as a result of poor head control due to the large size (Carolan et al feel that developmental delay without macrocrania runs counter to the concept of “benign” collections[77]), frontal bossing, jitteriness. The poor head control may lead to positional flattening. Other symptoms, such as seizures (possibly focal) are indicative of symptomatic collections (see below). Large collections in the absence of macrocrania are more suggestive of cerebral atrophy.

Treatment

Most cases gradually resolve spontaneously, often within 8–9 months. A single subdural tap (p. 1811) for diagnostic purposes (to differentiate from cortical atrophy and to rule out infection) may be done, and may accelerate the rate of disappearance. Repeat physical exams with OFC measurements should be done at ≈ 3–6 month intervals. Head growth usually parallels or approaches normal curves by ≈ 1–2 yrs of age, and by 30–36 months orbital-frontal head circumference (OFC) approaches normal percentiles for height and weight. They usually catch up developmentally as OFCs normalize.

64.8.3 Symptomatic chronic extraaxial fluid collections in children

General information

Variously classified as hematomas (chronic subdural hematoma), effusions, or hygromas, with differing definitions associated with each. Since the appearance on imaging and the treatment is similar, Litofsky et al proposed that they all be classified as extraaxial fluid collections.[79] The difference between these lesions and “benign” subdural effusions (see above) may simply be the degree of clinical manifestation.

Etiologies

The following etiologies were listed in a series of 103 cases[79]:
1. 36% were thought to be the result of trauma (22 were victims of child abuse)
2. 22% followed bacterial meningitis (post-infectious)
3. 19 occurred after placement or revision of a shunt (p. 464)
4. no cause could be identified in 17 patients

Other causes include[74]:
1. tumors: extracerebral or intracerebral
2. post-asphyxia with hypoxic brain damage and cerebral atrophy
3. defects of hemostasis: vitamin K deficiency…

Signs and symptoms

Symptoms include: seizure (26%), large head (22%), vomiting (20%), irritability (13%), lethargy (13%), headache (older children), poor feeding, respiratory arrest…

Signs include: full fontanelle (30%), macrocrania (25%), fever (17%), lethargy (13%), hemiparesis (12%), retinal hemorrhages, coma, papilledema, developmental delay…

Evaluation

CT/MRI usually shows ventricular compression and obliteration of the cerebral sulci, unlike with benign subdural collections. The “cortical vein sign” (p. 434) helps distinguish this from external hydrocephalus.

Treatment

Options include:
1. observation: follow-up with serial OFC measurements, ultrasound, and CT/MRI
2. serial percutaneous subdural taps (p. 1811): some patients require as many as 16 taps.[80] Some series show good results and others show low success rate[81,82]

3. burr hole drainage: may include long-term external drainage. Simple burr hole drainage may not be effective with severe craniocephalic disproportion since the brain will not expand to obliterate the extra-axial space
4. subdural-peritoneal shunt: unilateral shunt is usually adequate even for bilateral effusions[79,82,83] (recent recommendations: no study is required to demonstrate communication between the 2 sides[79,84]). An extremely low pressure system should be utilized. The general practice is to remove the shunt after 2–3 months of drainage (once the collections are obliterated) to reduce the risk of associated mineralization of the dura and arachnoid and possible risk of seizures (these shunts are easily removed at this time, but may be more difficult to remove at a later date)[85]

Other recommendations:

At least one percutaneous tap should be performed to rule out infection.

Many authors recommend observation for the patient with no symptoms or with only enlarging head and developmental delay.

64.9 Traumatic posterior fossa mass lesions

64.9.1 General information

Less than 3% of head injuries involve traumatic mass lesions of the posterior fossa.[86] Epidural hematomas (p. 1072) constitute the majority of these. The small remainder is comprised of subdural hematoma (see below and ▶ Fig. 64.8) and intraparenchymal hematoma[87]). Any of these can cause hydrocephalus[86] typically by displacing and compressing the 4th ventricle or its outlets. Until hydrocephalus develops, these hematomas may not produce elevated ICP using conventional monitoring techniques.

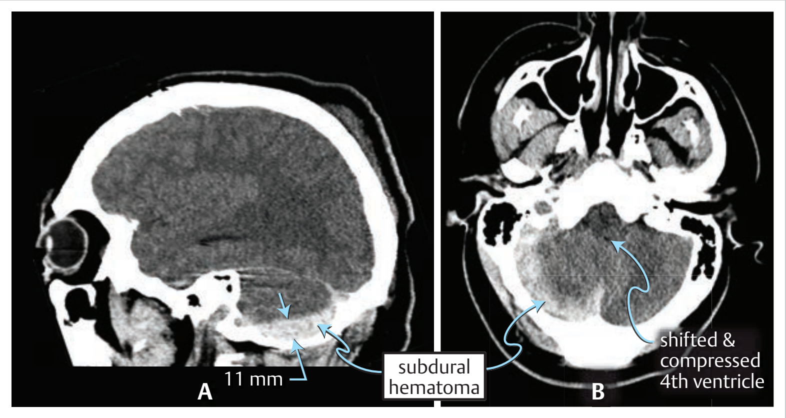

Fig. 64.8 Right-sided posterior fossa subdural hematoma.
Image: A: sagittal CT scan through the right cerebellar hemisphere. B: axial CT scan.

64.9.2 Posterior fossa subdural hematoma

Rare (comprise < 3% of TBIs[88]).

Based on case reports and retrospective series, the prognosis is poor (63% poor outcomes[88]).

64.9.3 Management

See **Practice guideline: Surgical management of traumatic posterior fossa mass lesions** (p. 1090) for surgical management recommendations.

Practice guideline: Surgical management of traumatic posterior fossa mass lesions

Indications for surgery

Level III[89]: symptomatic posterior fossa mass lesions or those with mass effect on CT should be surgically removed. **Note:** mass effect on CT: defined as dislocation, compression or obliteration of the 4th ventricle; compression or loss of basal cisterns (p. 1109) or the presence of obstructive hydrocephalus

- asymptomatic lesions without mass effect on CT may be managed with close observation and serial imaging

Timing of surgery

Level III[89]: p-fossa mass lesions meeting surgical criteria should be evacuated ASAP due to the potential for rapid deterioration

Surgical methods

Level III[89]: suboccipital craniectomy (not replacing the bone) as opposed to craniotomy, is the recommended procedure because post-op bleeding or swelling is poorly tolerated in the small confines of the posterior fossa

Most parenchymal hemorrhages managed nonsurgically were < 3 cm in diameter.

Other options for surgical intervention[88]:

- bilateral suboccipital decompression: consider for patients with GCS < 9 or if mass effect is present on the initial CT
- resection of posterior arch of C1: suggested if tonsillar herniation is evident
- ventriculostomy for post op monitoring/management: recommended if hydrocephalus is present

65 Gunshot Wounds and Non-Missile Penetrating Brain Injuries

65.1 Gunshot wounds to the head

65.1.1 General information

Gunshot wounds to the head (GSWH) account for the majority of penetrating brain injuries, and comprise ≈ 35% of deaths from brain injury in persons < 45 yrs old. GSWH are the most lethal type of head injury, ≈ two–thirds die at the scene, and GSWH ultimately are the proximal cause of death in > 90% of victims.[1]

65.1.2 Primary injury

Primary injury from GSWH results from a number of factors including:

1. injury to soft tissue
   a) direct scalp and/or facial injuries
   b) soft tissue and bacteria may be dragged intracranially, the devitalized tissue may also then support growth of the bacteria
   c) pressure waves of gas combustion may cause injury if the weapon is close
2. comminuted fracture of bone: may injure subjacent vascular and/or cortical tissue (depressed skull fracture). May act as secondary missiles
3. cerebral injuries from missile
   a) direct injury to brain tissue in path of bullet, exacerbated by
      - fragmentation of bullet
      - ricochet off bone
      - deviations of the bullet from a straight path as it travels: tumbling (forward rotation – pitch), yaw (rotation about vertical axis), rotation (spin), nutation (similar to precession or wobble)
      - deformation of bullet at impact: e.g., mushrooming
   b) injury to tissue by shock waves, cavitation
4. coup + contrecoup injury from missile impact on head (may cause injuries distant from bullet path)

Because of the complexities of ballistics (some of which are described above) there is often more damage distally than at the entry site even though the bullet slows (losing kinetic energy).

Extent of primary injury is related to *impact velocity*:

- *impact* velocity > 100 m/s: causes explosive intracranial injury that is uniformly fatal (NB: impact velocity is less than muzzle velocity)
- non-bullet missiles (e.g., grenade fragments) are considered low velocity
- low *muzzle* velocity bullets (≈ < 250 m/s): as with most handguns. Tissue injury is caused primarily by laceration and maceration along a path slightly wider than missile diameter
- high *muzzle* velocity bullets (≈ 600–750 m/s): from military weapons and hunting rifles. Causes additional damage by shock waves and temporary cavitation (tissue pushed away from the missile causes a conical cavity of injury that may exceed bullet diameter many-fold, and causes low-pressure region which may draw surface debris into the wound)

65.1.3 Secondary injury

Cerebral edema occurs similar to closed head injury. ICP may rise rapidly within minutes (higher ICPs result from higher impact velocities). Cardiac output may also fall initially. Together, ↑ ICP and ↓ MAP adversely affect cerebral perfusion pressure.

Other common complicating factors include: DIC, intracranial hemorrhage from lacerated blood vessels.

65.1.4 Late complications

Late complications include:

1. cerebral abscess: migration of bullet may be a tip-off (see below). Usually associated with retained contaminated material (bullet, bone, skin…) but may also result from persistent communication with nasal sinuses
2. traumatic aneurysm (p. 1491) [2]: typically in distal ACA (► Fig. 89.1)
3. seizures
4. fragment migration
   a) migration of a bullet: often indicates abscess[3] or, less commonly, a hematoma cavity. May also migrate within the ventricles
   b) intraventricular fragments may migrate and cause obstructive hydrocephalus[4]
5. lead toxicity (p. 1219): more of an issue with bullet in disc space

65.1.5 Evaluation

Physical exam

Exam should describe visible entrance and exit wounds. In through-and-through missile wounds of the skull, the entrance wound is typically smaller than the exit wound due to bullet mushrooming. Entrance wounds may be especially small with direct contact of the muzzle to the head. At surgery or autopsy, the entrance wound will typically show bevelling of the inner table, whereas exit wounds have a bevelled outer table.

Imaging

AP and lateral skull X-rays

This is one situation where skull X-rays still may provide useful information, as they are less susceptible to artifact from the bullet than the CT scan. Helps to localize metal and bone fragments, and to help identify entrance/exit sites (omit if time not available)

Head CT scan without contrast

The main assessment tool. Demonstrates location of bone and metal. Delineates bullet trajectory: assesses if bullet passed through ventricles and how many quadrants of the hemisphere have been traversed. Shows amount of blood in brain and assesses intracranial hematomas (epidural, subdural or intraparenchymal).

Angiography in GSWH

Rarely performed emergently. When done, usually performed on ≈ day 2–3.

Indications for angiography[5]:

- unexpected delayed hemorrhage
- a trajectory that would likely involve named vessels in a salvageable patient
- large intraparenchymal hemorrhages in a salvageable patient

65.1.6 Management

Initial management

General measures

1. CPR as required; endotracheal intubation if stuporous or airway compromised
2. additional injuries (e.g., chest wounds) identified and treated appropriately
3. usual precautions taken for spine injury
4. fluids as needed to replace estimated blood loss which may be variable: exercise restraint to avoid excessive hydration (to minimize cerebral edema)
5. pressors to support MAP during and after fluid resuscitation

Treatment specific to the injury

Neurological assessment as rapidly as possible and as thoroughly as time permits.

The Glasgow Coma Scale is still the most widely used grading system and allows better comparison between series than specialized scales for GSWHs.

Decision by experienced neurosurgeon regarding the ultimate treatment of the patient will determine appropriate steps to be taken. Patients with little CNS function (in the absence of shock) are unlikely to benefit from craniotomy; supportive measures are indicated in most of these cases with (for possibility of organ donation, opportunity for family to adjust to situation, and requirements for observation period to determine actual brain death).

In patients considered for further treatment, rapid deterioration at any point with signs of herniation requires immediate surgical intervention. As time permits, the following should be undertaken:

1. initial steps
   a) control bleeding from scalp and associated wounds (hemostats on scalp vessels)
   b) shave scalp to identify entrance/exit sites, and to save time in the O.R.
2. medical treatment (similar to closed head injury)
   a) assume ICP is elevated:
      - elevate HOB 30–45° with head midline (avoids kinking jugular veins)
      - mannitol (1 gm/kg bolus) as blood pressure tolerates
      - hyperventilate to $PaCO_2 = 30–35$ mm Hg if indications are met (p. 1053)
      - steroids: (unproven efficacy) 10 mg dexamethasone IVP
   b) prophylaxis against GI ulcers: H2 antagonist (e.g., ranitidine 50 mg IVPB q 8 hrs) or proton pump inhibitor, NG tube to suction
   c) begin antiseizure medications (does not reduce incidence of late seizures)
   d) antibiotics: generally used although no controlled study demonstrates efficacy in preventing meningitis or abscess. Most organisms are sensitive to penicillinase resistant agents, e.g., *nafcillin*, recommended for ≈ 5 days
   e) tetanus toxoid administration

Surgical treatment

Indications for surgery are controversial. Some authors suggest that better outcome might occur with more aggressive management, and that poor outcome may be a self-fulfilling prophecy.[6] Patients with minimal neurologic function, e.g., fixed pupils, decorticate or decerebrate posturing… (when not in shock and with good oxygenation) should *not* be operated upon, because the chance of meaningful recovery is close to zero. Patients with less severe injuries should be considered for urgent operation.

Goals of surgery

1. debridement of devitalized tissue: less tissue is injured in civilian GSWH, but elevated ICP post-op may imply more vigorous debridement was needed, especially of non-eloquent brain (e.g., temporal tips)
2. evacuation of hematomas: subdural, intraparenchymal…
3. removal of *accessible* bone fragments
4. retrieval of bullet fragment for forensic purposes (note: everyone who handles the fragments may be subpoenaed to testify as to the “chain of evidence”). Large intact fragments should be sought as they tend to migrate (**note:** risk of infection and seizures due to retained bullet fragments is not high in civilian GSWH; therefore only accessible fragments should be sought and removed)
5. obtaining hemostasis
6. watertight dural closure (usually requires graft)
7. separation of intracranial compartment from air sinuses traversed by bullet
8. identification of entry and exit wounds for forensic purposes; see Evaluation (p. 1094)

Surgical technique

Some key points of surgical technique[7 (p 2098–104)]:

- positioning and draping should make both entry and exit wounds accessible
- devitalized tissue around the entry & exit wounds should be excised
- fractured bone should be excised by a circumferential craniectomy (craniotomy may be used in some civilian GSWH; the entry site within the craniotomy should be rongeured or drilled back to clean bone)
- air sinuses that are traversed should have the mucosa exenterated, and are then packed with muscle, and covered with a graft (e.g., periosteum or fascia lata) to separate them from intracranial compartment
- the dura is opened in a stellate fashion

- pulped brain is removed from within using suction and bipolar in an enlarging cone until healthy tissue is encountered (further injury to deep midline structures should be avoided, here, stay within bullet tract)
- contralateral fragments with no exit wound should only be removed if accessible
- intraventricular fragments can present significant risk. Ventriculoscopy (if available) may be well suited for removing these
- dural closure should be watertight; grafts of pericranium, temporalis fascia, or fascia lata grafts may be used; avoid dura substitutes
- cranioplasty should be delayed 6–12 months to reduce risk of infection
- a post-op CSF fistula that persists > 2 weeks should be repaired

ICP monitoring

ICP is often elevated after surgical debridement[6] and monitoring may be warranted.

Outcome

Prognostic factors:

1. level of consciousness is the most important prognostic factor: ≈ 94% of patients who are comatose with inappropriate or absent response to noxious stimulus on admission die, and half the survivors are severely disabled[8]
2. as initially espoused by Cushing, the path of the bullet is also an important prognosticator. Especially *poor prognosis* is associated with:
   a) bullets that cross the midline
   b) bullets that pass through the geographic center of the brain
   c) bullets that enter or traverse the ventricles
   d) the more lobes traversed by the bullet
3. hematomas seen on CT are poor prognostic findings
4. suicide attempts are more likely to be fatal

65.2 Non-missile penetrating trauma

65.2.1 General information

This section deals with penetrating injuries to the brain (and to some extent to the spinal cord) excluding missile injuries, i.e., gunshot wounds (p. 1093). Includes trauma from: knives, arrows, lawn darts… Injury to neural tissue tends to be more limited than with missiles because many of the associated injurious aspects of the missile are absent (p. 1093).

65.2.2 Arrow injuries

As a result of the lower velocity (e.g., 58 m/s) compared to firearms and the sharp tip, injury is usually limited to tissue directly incised by the arrowhead.[9]

65.2.3 Cases with foreign body still embedded

In penetrating trauma, it is usually not appropriate to remove any protruding part of the foreign body until the patient is in the operating room, unless it cannot be avoided. If possible, it is helpful to have another identical object for comparison in planning extrication of the embedded object.[10] To minimize extending the trauma to the CNS, the protruding object should be stabilized in some way during transportation and evaluation. Intraoperatively, devices such as the Greenberg retractor may be used to stabilize the object during preparation and the initial approach.

65.2.4 Indications for pre-op angiography

1. object passes in region of large named artery
2. object passes near dural sinuses
3. visible evidence of arterial bleeding: angiography is not appropriate if hemorrhage cannot be controlled

65.2.5 Surgical techniques

It is impossible to give details to cover every situation. Some guidelines:

1. empiric antibiotic coverage is appropriate; see Meningitis post craniospinal trauma (p. 340). Take cultures from the wound and the foreign body to guide later antibiotic therapy
2. optimal control can usually be gained by performing a craniotomy up to and if possible around the object, such that removing the bone flap will not disturb the object. The last remnants of bone may then be removed with a rongeur
3. if at all possible open the dura before removing the object, since removal with the dura closed does not allow adequate control of any bleeding from the brain
4. removal of the object ideally should follow the entry trajectory if possible
5. although gunshot wounds are not sterile as once thought, they are probably less contaminated than penetrating wounds. One should debride any easily accessible impacted bone and other extracranial tissue and material along the track

65.2.6 Post-op care

1. a course of antibiotics are usually appropriate since infection is common
2. consider a post-op arteriogram to rule out traumatic aneurysm

66 Pediatric Head Injury

66.1 Epidemiology of pediatric head injury and comparison to adults

75% of children hospitalized for trauma have a head injury. Although most pediatric head injuries are mild and involve only evaluation or brief hospital stays, CNS injuries are the most common cause of pediatric traumatic death.[1] The overall mortality for all pediatric head injuries requiring hospitalization has been reported between 10–13%,[2] whereas the mortality associated with severe pediatric head injury presenting with decerebrate posturing has been reported as high as 71%.[3]

Differences between adult and pediatric head injury:

1. epidemiology:
   a) children often have milder injuries than adults
   b) lower chance of a surgical lesion in a comatose child than in an adult[4]
2. types of injury: injuries peculiar to pediatrics
   a) birth injuries: skull fractures, cephalhematoma (see below), subdural or epidural hematomas, brachial plexus injuries (p. 579)
   b) perambulator/walker injuries
   c) nonaccidental trauma (p. 1103) (NAT) (formerly child abuse): shaken baby syndrome…
   d) injuries from skateboarding, scooters…
   e) injuries related to the easier penetrability of the pediatric skull: e.g., recreational lawn darts
   f) cephalhematoma: see below
   g) leptomeningeal cysts, AKA “growing skull fractures” (p. 1100)
   h) retroclival hematoma (p. 1102)
3. response to injury
   a) responses to head injury of older adolescents are very similar to those of adults
   b) “malignant cerebral edema”: acute onset of severe cerebral swelling (probably due to hyperemia[5,6]) following some head injuries, especially in young children (may not be as common as previously thought[7])
   c) posttraumatic seizures: more likely to occur within the first 24 hrs in children than in adults (p. 505) [8]

66.2 Management

66.2.1 Imaging studies

The PECARN algorithm[9] identified children with mTBI (GCS = 14–15) having a very low risk of clinically-significant brain injuries resulting in these recommendations regarding CT scan:

1. children < 2 years of age
   a) GCS = 14 or other signs of altered mental status or palpable skull fracture: CT recommended
   b) occipital or parietal or temporal scalp hematoma, or history of LOC ≥ 5 seconds, or severe mechanism of injury, or not acting normally according to the parent: CT vs. observation based on physician experience, multiple vs. isolated findings, worsening signs or symptoms after observation in E/R, and ≤ 3 months, parental preference
   c) all others: CT not recommended
2. children ≥ 2 years age
   a) GCS = 14 or other signs of altered mental status, or signs of basilar skull fracture: CT recommended
   b) history of LOC, or history of vomiting, or severe mechanism of injury, or severe H/A: CT vs. observation based on physician experience, multiple vs. isolated findings, worsening signs or symptoms after observation in E/R, parental preference
   c) all others: CT not recommended

Practice guideline: Imaging in minor pediatric head injury

- Level B[10]: CT scans should not be routinely used for children with mild TBI.
- Level B[10]: validated clinical decision rules (such as the PECARN algorithm described above) should be used to identify children at low risk for clinically significant TBI in whom CT is not indicated.
- Level B[10]: brain MRI imaging should not routinely be used in the acute evaluation of suspected or diagnosed mTBI*

*Rapid sequence MRI in nonsedated patients has been successfully used[11] but was not included in the guidelines

66.2.2 Home observation

Practice guideline: Home observation in minor pediatric head injury

Recommendations*: a child with GCS = 14–15 and normal CT scan can be considered for home observation if neurologically stable (these patients are at near zero risk of having an occult brain injury).

*Based mostly on prospective trials (not randomized) or large case series.

Definitions: pediatrics = ages 1 month–17 years of age. Minor head injury: GCS ≥ 13 (excludes: suspicion or proof of child abuse, patients requiring hospitalization for other reasons).

66.3 Outcome

As a group, children fare better than adults with head injury.[12] However, very young children do not do as well as the school-age child.[13]

All aspects of neuropsychological dysfunction following head injury may not always be related to the trauma, as children who get injured may have pre-existing tendencies that increased their propensity to get hurt[14] (this is controversial[15]).

66.4 Cephalhematoma

66.4.1 General information

Accumulation of blood under the scalp. Occurs almost exclusively in children.

Two types:

1. subgaleal hematoma: may occur without bony trauma, or may be associated with linear nondisplaced skull fracture (especially in age < 1 yr). Bleeding into loose connective tissue separates galea from periosteum. May *cross sutures*. Usually starts as a small localized hematoma, and may become huge (with significant loss of circulating blood volume in age < 1 year, transfusion may be necessary). Inexperienced clinicians may suspect CSF collection under the scalp which does not occur. Usually presents as a soft, fluctuant mass. These do *not* calcify
2. subperiosteal hematoma (some refer to this as cephalhematoma): most commonly seen in the newborn (associated with parturition, may also be associated with neonatal scalp monitor[16,17]). Bleeding elevates periosteum, extent is *limited by sutures*. Firmer and less ballotable than subgaleal hematoma[18 (p 312)]; scalp moves freely over the mass. 80% reabsorb, usually within 2–3 weeks. Occasionally may calcify

Infants may develop jaundice (hyperbilirubinemia) as blood is resorbed, occasionally as late as 10 days after onset.

66.4.2 Treatment

Treatment beyond analgesics is almost never required, and most usually resolve within 2–4 weeks. Avoid the temptation of percutaneously aspirating these because the risk of infection exceeds the risk of following them expectantly, and in the newborn removal of the blood may make them anemic. Follow serial hemoglobin and hematocrit in large lesions. If a subperiosteal hematoma persists > 6 weeks, obtain a skull film. If the lesion is calcified, surgical removal may be indicated for cosmetic reasons (although with most of these the skull will return to normal contour in 3–6 months).[18 (p 315)]

66.5 Skull fractures in pediatric patients

66.5.1 General information

This section deals with some special concerns of skull fractures in pediatrics. Also see Child abuse (p. 1103).

66.5.2 Posttraumatic leptomeningeal cysts (growing skull fractures)

General information

Posttraumatic leptomeningeal cysts (PTLMC) (sometimes just traumatic leptomeningeal cysts), AKA growing skull fractures, are not to be confused with arachnoid cysts (AKA leptomeningeal cysts, which are not posttraumatic). PTLMC consists of a fracture line that widens with time. Although usually asymptomatic, the cyst may cause mass effect with neurologic deficit.

PTLMCs were first described in 1816,[19] and are *very* rare, occurring in 0.05–0.6% of skull fractures.[20,21] Usually requires both a widely separated fracture AND a dural tear. Mean age at injury: < 1 year; over 90% occur before age 3 years[22] (formation may require the presence of a rapidly growing brain[23]), although rare adult cases have been described[19,24,25] (a total of 5 cases in the literature as of 1998[19]). PTLMCs rarely occur > 6 mos out from the injury. Some children may develop a skull fracture that seems to grow during the initial few weeks that is *not* accompanied by a subgaleal mass, and that heals spontaneously within several months; the term "pseudogrowing fracture" has been suggested for these.[26]

Presentation

Most often presents as scalp mass (usually subgaleal), although there are reports of presentation with head pain alone.[24]

Diagnosis

Radiographic findings: progressive widening of fracture and scalloping (or saucering) of edges.

Screening for development of PTLMC

If early growth of a fracture line with no subgaleal mass is noted, repeat skull films in 1–2 months before operating (to rule out pseudogrowing fracture). In young patients with separated skull fractures (the width of the initial fracture is rarely mentioned), consider obtaining follow-up skull film 6–12 mos post-trauma. However, since most PTLMCs are brought to medical attention when the palpable mass is noticed, routine follow-up X-rays may not be cost-effective.

Treatment

Treatment of true PTLMC is surgical, with dural closure mandatory. Since the dural defect is usually larger than the bony defect, it may be advantageous to perform a craniotomy around the fracture site, repair the dural defect, and replace the bone.[25] Pseudogrowing fractures should be followed with X-rays and operated only if expansion persists beyond several months or if a subgaleal mass is present.

66.5.3 Depressed skull fractures in pediatrics

See reference.[27]

General information

Most common in frontal and parietal bones. One third are closed, and these tend to occur in younger children (3.4 ± 4.2 yrs, vs. 8.0 ± 4.5 yrs for compound fractures) as a result of the thinner, more deformable skull. Open fractures tended to occur with MVAs, closed fractures tended to follow accidents at home. Dural lacerations are more common in compound fractures.

Simple depressed skull fractures

There was no difference in outcome (seizures, neurologic dysfunction or cosmetic appearance) in surgical vs. nonsurgical treatment in 111 patients < 16 yrs of age. In the younger child, remodelling of the skull as a result of brain growth tends to smooth out the deformity.

Indications for surgery for pediatric simple depressed skull fracture:

1. definite evidence of dural penetration
2. persistent cosmetic defect in the older child after the swelling has subsided
3. ± focal neurologic deficit related to the fracture (this group has a higher incidence of dural laceration, although it is usually trivial)

“Ping-pong ball” fractures

See reference.[28]

A green-stick type of fracture → caving in of a focal area of the skull as in a crushed area of a ping-pong ball. Usually seen only in the newborn due to the plasticity of the skull.

Indications for surgery

No treatment is necessary when these occur in the temporoparietal region in the absence of underlying brain injury as the deformity will usually correct as the skull grows.

- radiographic evidence of intraparenchymal bone fragments
- associated neurologic deficit (rare)
- signs of increased intracranial pressure
- signs of CSF leak deep to the galea
- situations where the patient will have difficulty getting long-term follow-up

Technique

Frontally located lesions may be corrected for cosmesis by making a small linear incision behind the hairline, opening the cranium adjacent to the depression, and pushing it back out e.g., with a Penfield #3 dissector.

66.5.4 Dural sinus thrombosis/compression in pediatric skull fractures

► **The issue.** There is concern that a cerebral dural (venous) sinus thrombosis (DST) and/or compression may be associated with a skull fracture in the vicinity of dural venous sinuses, and that outcome in these cases will be worse if not treated with anticoagulation. Therefore there is a trend to evaluate pediatric patients with skull fractures for DST using CTV (which often involves additional radiation) or MRV, with the possible need for anesthesia.

► **The data.** DST is rare in pediatrics. Incidence: 0.67 per 100,000 children per year.[29]

DST is found in 4% of patients with *penetrating* head trauma.

Anticoagulation is recommended in children with DST (Level II[30]) to reduce the incidence of thrombus propagation, venous infarction and poor outcome.[31]

In a series of 2224 pediatric patients with skull fractures following *blunt* trauma, 41 patients (2%) had venous imaging (most because of proximity of the fracture to a dural sinus), 8 of those (20%) had DST, 14 (34%) had extrinsic sinus compression, 3 patients with DST developed venous infarcts.[29]

► **Recommendation.** For pediatric patients with skull fractures following *blunt* trauma, venous imaging (CTV or MRV) is recommended only when venous hypertension or venous infarction is suspected and anticoagulation is considered.[29]

66.6 Retroclival hematoma

66.6.1 General information

Key concepts

- rare. Predilection for pediatrics, where it usually occurs with trauma (e.g., MVA)
- significant because it may be associated with atlantooccipital dislocation (AOD)
- usually managed conservatively with brace (e.g., halo or SOMI)
- outcome is usually good. Death can occur usually from other causes

A rare disorder. May occur following trauma, especially with violent hyperflexion or hyperextension of the neck usually in association with motor vehicle accidents. Predilection for pediatrics, possibly due to the higher ratio of head to body weight, flatter occipital condyles, and increased ligamentous laxity in children. It may also occur without trauma, more likely in adults e.g., with pituitry apoplexy, anticoagulation, subarachnoid hemorrhage…[32]

Blood can be epidural (anterior to the tectorial membrane (p. 67)) or subdural (posterior to tectorial membrane) or a combination, and may originate from fracture or ligamentous disruption.[33]

May be associated with:

- atlantooccipital dislocation (p. 1153) [34,35]
- occipital condyle fracture (p. 1156)
- disruption of the apical odontoid ligament (p. 69)
- fracture of the clivus
- odontoid fracture

66.6.2 Presentation

Neurologic findings may be due to stretching, compression, or contusion of adjacent brain parenchyma or nerves.[33]

Cranial nerve involvement reported includes:

- abducens (VI): the most commonly involved cranial nerve. May be unilateral or bilateral[33]
- optic (II)
- oculomotor (III)
- trigeminal (V)
- facial (VII)
- glossopharyngeal (IX)
- hypoglossal (XII)
- spinal accessory nerve (XI)

Other presentations include:

- hemiparesis
- quadriparesis
- hydrocephalus[34]
- occipitocervical instability

66.6.3 Evaluation

Noncontrast MRI is the imaging modality of choice. Demonstrates the hematoma (acutely may be best seen on T2WI), DWI assesses for stroke, and STIR images (p. 241) to look for signal changes indicative of ligamentous injury (▶ Fig. 66.1).

CT including coronal reconstructions is useful to look for occipital condyle fractures, avulsion of the apical igament, and to assess the atlantooccipital interval (p. 1154) (surrogate marker for atlantooccipital dislocation (p. 1153))

Evaluation e.g., with CTA for concurrent blunt cerebrovascular injury (p. 1029) may be appropriate in some instances (especially if stroke is suspected or demonstrated on MRI).

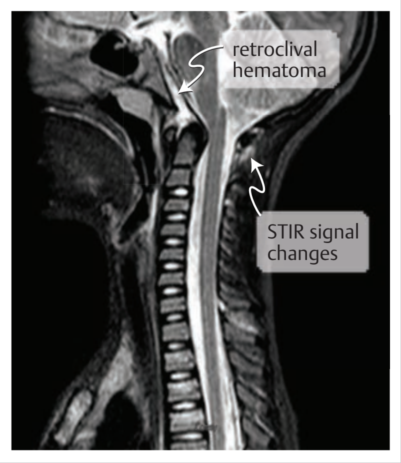

Fig. 66.1 Retroclival epidural hematoma.
6-year-old with atlantooccipital dislocation (AOD) following motor vehicle accident.
Sagittal STIR MRI.

66.6.4 Management

Most cases are managed conservatively, usually with a brace (halo/vest, SOMI…).

Indications for surgical interventions include:

- fusion: may be considered as follows
  - strong indication: ligamentous instability e.g., atlantooccipital dislocation meeting AOD surgical criteria (p. 1156)
  - soft indication: cranial nerve deficits
- evacuation of hematoma: indicated on rare occasion for symptomatic brainstem compression[36]
- ventriculostomy/shunt: indicated for hydrocephalus

66.6.5 Outcome

The hematoma generally resolves in 2–11 weeks.[33]

Conservative management results in good outcomes with minimal long-term neurologic deficits in the majority of cases.

Death occurs infrequently, and usually from other causes in patients who are neurologically devastated on admission.[33]

66.7 Nonaccidental trauma (NAT)

66.7.1 General information

AKA child abuse. At least 10% of children < 10 yrs of age that are brought to E/R with alleged accidents are victims of NAT.[37] The incidence of accidental head trauma of significant consequence below age 3 is low, whereas this is the age group in which battering (abuse) is highest.[38]

There are no findings that are pathognomonic for child abuse. Factors which raise the index of suspicion include:

1. retinal hemorrhage (see below)
2. bilateral chronic subdural hematomas in a child < 2 yrs of age (p. 1088)
3. skull fractures that are multiple (see below) or those that associated with intracranial injury
4. significant neurological injury with minimal signs of external trauma
5. multiple injuries of different ages in multiple locations

66.7.2 Shaken baby syndrome

Vigorous shaking of a child produces violent whiplash-like angular acceleration-decelerations of the head (the infant head is relatively large in proportion to the body, and the neck muscles are comparatively weak),[39] which may lead to significant brain injury. Some researchers believe that shaking alone may be inadequate to produce the severe injuries seen, and that impact is often also involved.[40]

Characteristic findings include retinal hemorrhages (see below), subdural hematomas (bilateral in 80%) and/or subarachnoid hemorrhage (SAH). There are usually few or no external signs of trauma (including cases with impact, although findings may be apparent at autopsy). In some cases there may be finger marks on the chest, multiple rib fractures and/or pulmonary compression ± parenchymal lung hemorrhage. Deaths in these cases are almost all due to uncontrollable intracranial hypertension. There may also be injury to the cervicomedullary junction.[41]

66.7.3 Retinal hemorrhage (RH) in child abuse

"In a traumatized child with multiple injuries and an inconsistent history, the presence of RH is pathognomonic of battering."[38] However, RH may also occur in the absence of any evidence of child abuse. 16/26 battered children < 3 yrs of age had RH on funduscopy, whereas 1/32 non-battered traumatized children with head injury had RH (the single false positive: traumatic parturition, where the incidence of RH is 15–30%).

Differential diagnosis of etiologies of retinal hemorrhage:

1. child abuse (including "shaken baby syndrome," see above)
2. benign subdural effusion in infants (p. 1087)
3. acute high altitude sickness (p. 1028)
4. acute increase in ICP: e.g., with a severe seizure (may be similar to Purtscher's retinopathy—see below)
5. Purtscher's retinopathy[42]: loss of vision following major trauma (chest crush injuries, airbag deployment[43]…), pancreatitis, childbirth or renal failure, among others. Posterior pole ischemia with cotton-wool exudates and hemorrhages around the optic disc due to microemboli of possibly fat, air, fibrin clots, complement-mediated aggregates, or platelet clumps. No known treatment

66.7.4 Skull fractures in child abuse

A series comparing 39 cases of skull fracture from documented child abuse to 95 cases of probable accidental injury[37] showed the following:

1. the parietal bone was the most common site of fracture in both groups (≈ 90%)
2. depression of skull fractures was frequently missed clinically due to overlying hematoma
3. clinical features in patients with skull fractures did not reliably differentiate child abuse from trauma (retinal hemorrhages (RH) were seen in 1 child abuse and 1 accidental trauma patient: note that RH is more common in "shaken child" syndrome which is not commonly associated with skull fractures)
4. 3 characteristics more frequently seen after child abuse than after other trauma:
    a) multiple fractures
    b) bilateral fractures
    c) fractures that cross sutures

67 Head Injury – Long-Term Management, Complications, Outcome

67.1 Airway management

Practice guideline: Airway management

- Timing of tracheostomy (Level II[1]): early tracheostomy reduces the number of days of mechanical ventilation but does not affect mortality or incidence of pneumonia
- Timing of extubation (Level III[1]): early extubation for patients meeting extubation criteria does not increase the risk of pneumonia

67.2 Deep-vein thrombosis (DVT) prophylaxis

Also see further details about thromboembolism (p. 176) in neurosurgical patients. The risk of developing DVT is ≈ 20% in untreated severe TBI.[2] See also **Practice guideline: DVT prophylaxis in severe TBI** (p. 1106).

Practice guideline: DVT prophylaxis in severe TBI

Level III[3]:

- unless contraindicated, graduated compression stockings or intermittent compression boots are recommended until patients are ambulatory
- low molecular weight heparin (LMWH) (p. 172) or low-dose unfractionated heparin in conjunction with mechanical measures lowers the DVT risk, but a trend suggests they increase the risk of expansion of intracranial hemorrhage (**note:** there is insufficient evidence to support use of one pharmacologic agent over another, or to define the optimal dose or timing of agents[3])

67.3 Nutrition in the head-injured patient

67.3.1 Summary of recommendations (see text for details)

Practice guideline: Nutrition

Level II[4]: full caloric replacement should be attained by post-trauma day 7

Σ: Nutrition goals following TBI

1. by post-trauma day 7, replace the following (enterally or parenterally):
   a) non-paralyzed patients: 140% of predicted basal energy expenditure (BEE)
   b) paralyzed patients: 100% of predicted BEE
2. provide ≥ 15% of calories as protein
3. nutritional replacement should begin within 72 hrs of head injury in order to achieve goal #1 by day 7
4. the enteral route is preferred (IV hyperalimentation is preferred if higher nitrogen intake is desired or if there is decreased gastric emptying)

67.3.2 Caloric requirements

Rested comatose patients with isolated head injury have a metabolic expenditure that is 140% of normal for that patient (range: 120–250%).[5,6,7,8] Paralysis with muscle blocker or barbiturate coma reduced this excess expenditure in most patients to ≈ 100–120% of normal, but some remained elevated by 20–30%.[9] Energy requirements rise during the first 2 weeks after injury, but it is not known for how long this elevation persists. Mortality is reduced in patients who receive full caloric replacement by day 7 after trauma[10] (a beneficial effect with an earlier goal of replacement by 3 days post-trauma was not found[11]). Since it generally takes 2–3 days to get nutritional replacement up to speed whether the enteral or parenteral route is utilized,[8] it is recommended that nutritional supplementation begin within 72 hrs of head injury.

67.3.3 Enteral vs. IV hyperalimentation

Caloric replacement that can be achieved is similar between enteral or parenteral routes.[12] The enteral route is preferred because of reduced risk of hyperglycemia, infection, and cost.[13] IV hyperalimentation may be utilized if higher nitrogen intake is desired or if there is decreased gastric emptying. No significant difference in serum albumin, weight loss, nitrogen balance, or final outcome was found between enteral and parenteral nutrition.[12]

Estimates of basal energy expenditure (BEE) can be obtained from the Harris-Benedict equation,[14] shown in Eq (67.1), (67.2), and (67.3), where W is weight in kg, H is height in cm, and A is age in years.

$$\text{Males}: \ \text{BEE} = 66.47 + 13.75 \times W + 5.0 \times H - 6.76 \times A \tag{67.1}$$

$$\text{Females}: \ \text{BEE} = 655.1 + 9.56 \times W + 1.85 \times H - 4.68 \times A \tag{67.2}$$

$$\text{Infants}: \ \text{BEE} = 22.1 + 31.05 \times W + 1.16 \times H \tag{67.3}$$

67.3.4 Enteral nutrition

Isotonic solutions (such as Isocal® or Osmolyte®) should be used at full strength starting at 30 ml/hr. Check gastric residuals q 4 hrs and hold feedings if residuals exceed ≈ 125 ml in an adult. Increase the rate by ≈ 15–25 ml/hr every 12–24 hrs as tolerated until the desired rate is achieved.[15] Dilution is not recommended (may slow gastric emptying), but if it is desired, dilute with normal saline to reduce free water intake.

Cautions:

- NG tube feeding may interfere with absorption of phenytoin; see phenytoin (PHT, Dilantin®) (p. 488).
- reduced gastric emptying may be seen following head-injury[16] (NB: some may have temporarily elevated emptying) as well as in pentobarbital coma; patients may need IV hyperalimentation until the enteric route is usable. The technique of hypocaloric feeding[17] (AKA "trophic feed," "trickle feed," among others)through an enteral feeding tube (e.g., Dobhoff tube) at a rate variously defined as at 10–20 ml/hr may be tolerated and may reduce mucosal atrophy while providing a portion of nutritional requirements. Others have described better tolerance of enteral feedings using jejunal administration[18]

67.3.5 Nitrogen balance

A normal subject fed a protein-free diet for 3 days will excrete 85 mg of nitrogen/kg/d. These losses increase with injury. The rise in urinary N is due primarily to an increase in urea (comprises 80–90% of urinary N). This is thought to represent an increase in mobilization and breakdown of amino acids, which are felt to originate mainly from skeletal muscle.[19] Some of this represents a primary reaction to injury in which certain vital organs seem to be maintained at the expense of less active organs, and a significantly higher nitrogen balance cannot be achieved by increasing the amount of calories supplied as protein beyond a certain level.[12,15] Catabolism of protein yields 4 kcal/g (the same as for carbohydrates, compared to 9 kcal/g for fat), and in the non-injured adult normally supplies only ≈ 10% of energy needs.[20]

As an estimate, for each gram of N excreted (mostly in the urine; however, some is also lost in the feces), 6.25 gm of protein have been catabolized. It is recommended that at least 15% of calories be supplied as protein. The percent of calories consumed (PCC) derived from protein can be calculated from Eq (67.4), where N is nitrogen in grams, and BEE is the basal energy expenditure[5] (see Eq (67.1), (67.2), and (67.3)).

$$\text{PCC (from protein)} = \frac{\text{N (gm N)} \times \frac{\text{6.25 gm protein}}{\text{gm N}} \times \frac{\text{4.0 kcal}}{\text{gm protein}}}{\text{BEE}} \times 100 \qquad (67.4)$$

Thus, to supply PCC (protein) = 15% once the BEE is known, use Eq (67.5). Some enteral formulations include Magnacal® (PCC = 14%) and TraumaCal® (PCC = 22%).

$$\text{N (gm N)} = 0.006 \times \text{BEE} \qquad (67.5)$$

67.4 Posttraumatic hydrocephalus

67.4.1 General information

Hydrocephalus was found in 40% of 61 patients with severe head injury (GCS = 3–8) and in 27% of 34 patients with moderate head injury (GCS = 9–13).[21] Hydrocephalus developed by 4 weeks after injury in 58% and by 2 months in 70%.[21] There was no statistically significant relationship between posttraumatic hydrocephalus and age, the presence of SAH, or type of lesion (focal or diffuse). Posttraumatic hydrocephalus was associated with worse outcome.[21]

Hydrocephalus after traumatic subarachnoid hemorrhage

Incidence of clinically **symptomatic** hydrocephalus within 3 months of traumatic subarachnoid hemorrhage (tSAH) is ≈ 12%.[22] In this series of 301 tSAH patients, multivariate analysis showed the risk of developing hydrocephalus increased with age, intraventricular hemorrhage, blood thickness ≥ 5 mm, and diffuse distribution of blood (vs. focal distribution). There was *no* correlation with gender, admission GCS score, basal location of tSAH, or use of decompressive craniectomy.[22] NB: this is potentially confusing; univariate analysis shows the risk of hydrocephalus increases with increasing severity of TBI.

67.4.2 Differentiating true hydrocephalus from hydrocephalus ex vacuo

Delayed ventricular enlargement months to years after TBI may instead be due to atrophy (hydrocephalus ex vacuo) secondary to diffuse axonal injury, and may not represent true hydrocephalus. It may not be possible to accurately differentiate these two conditions, and the decision to shunt may therefore be difficult (similar to the dilemma in patients with NPH vs. atrophy).

67.4.3 Indications for surgical treatment

Factors favoring hydrocephalus, for which shunt should be considered:
1. elevated pressure on 1 or more LPs
2. papilledema on funduscopic exam
3. symptoms of headache/pressure
4. findings of “transependymal absorption” (p. 441) on CT or T2WI MRI
5. ± patients whose neurologic recovery seems worse than expected
6. provocative tests e.g., to test CSF Ro (p. 444) have been recommended[23]

Patients with enlarged ventricles who are asymptomatic and are doing well following their head injury should be managed expectantly.

67.5 Outcome from head trauma

67.5.1 Age

In general, the degree of recovery from closed head injury is better in infants and young children than in adults. In adults, decerebrate posturing or flaccidity with loss of pupillary or oculovestibular reflex is associated with a poor outcome in most cases; these findings are not as ominous in pediatrics.

67.5.2 Outcome prognosticators

General information

The frequency of poor outcome from closed head injury is increased with persistent ICP > 20 mm Hg after hyperventilation, increasing age, impaired or absent pupillary light response or eye movement, hypotension (SBP < 90), hypercarbia, hypoxemia, or anemia.[24] This is probably due at least in part to the fact that some of these are markers for significant injury to other body systems. One of the most important predictors for poor outcome is the presence of a mass lesion requiring surgical removal.[25] High ICP during the first 24 hrs is also a poor prognosticator.

Obliteration of basal cisterns on CT

The status of the basal cisterns (BCs) is evaluated on axial CT scan at the level of the midbrain (▶ Fig. 67.1) where they are divided into 3 limbs[26] (1 posterior limb = quadrigeminal cistern, 2 lateral limbs = posterior portion of the ambient cisterns). **Note:** "basal cisterns" in the trauma literature are a subset of the perimesencephalic cisterns (p. 1497). Possible findings:

1. open: all 3 limbs open
2. partially closed: 1 or 2 limbs obliterated
3. completely closed: 3 limbs obliterated

Compression or absence of the BCs carries a threefold risk of increased ICP, and the status of the BCs correlates with outcome.[26]

In a study of 218 patients with GCS ≤ 8, the BCs were classified on initial CT (within 48 hrs of admission) as: absent, compressed, normal, or not visualized (quality of CT too poor to tell).[27] The relationship of the BCs to outcome is shown in ▶ Table 67.1.

18 patients had a shift of brain structures > 15 mm associated with absent BCs; all of them died. The status of the BCs were more important within each GOS score than across scores. Also, see ▶ Table 64.4 for further information on CT.

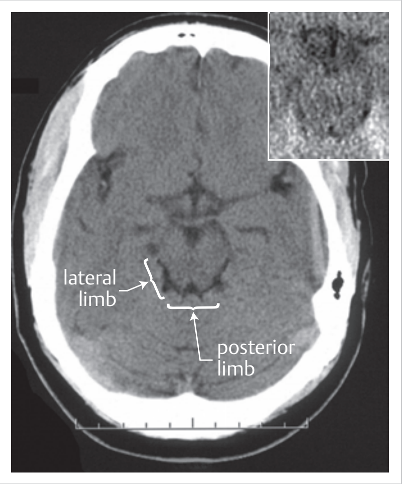

Fig. 67.1 Basal cisterns.
Axial brain CT demonstrating *open* basal cisterns (inset: example of ≈ complete obliteration of BCs).

Table 67.1 Correlation of GOS[a] with basal cisterns

Basal cisterns	Outcome[a]				
	Mortality	Vegetative	Severe disability	Moderate disability	Good
	(GOS 1)	(GOS 2)	(GOS 3)	(GOS 4)	(GOS 5)
normal	22%	6%	16%	21%	35%
compressed	39%	7%	18%	17%	19%
absent	77%	2%	6%	4%	11%
not-visualized	68%	0%	11%	9%	12%

[a] GOS = Glasgow outcome scale, see ▶ Table 98.4

Midline shift (MLS)

The presence of MLS correlates with a worse outcome. For the purpose of standardizing measurements in trauma, MLS is defined at the level of the foramen of Monro[26] as shown in ▶ Fig. 67.2, and is calculated using Eq (67.6).

$$\text{midline shift (MLS)} = \frac{\text{BPD}}{2} - \text{SP} \qquad (67.6)$$

where the midline shift is found by dividing the biparietal diameter (BPD) (the width of intracranial compartment at this location) by 2, and subtracting SP (the distance from the inner table to the septum pellucidum on the side of the shift). Measurements may be inaccurate if the vertical axis of the patient's head is not parallel to the long axis of the CT scanner.

Midline shift may be associated with altered levels of consciousness (p. 320).

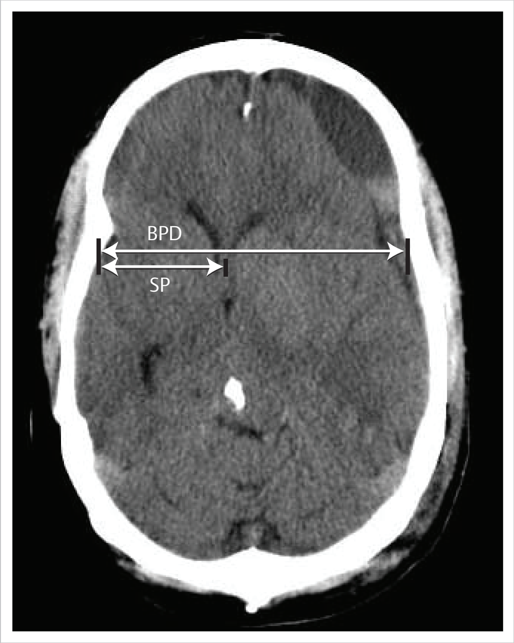

Fig. 67.2 Measurement of midline shift.
Axial noncontrast CT of a brain with a left-sided acute-on-chronic subdural hematoma.
Abbreviations: BPD = biparietal diameter (distance from inner table to inner table at the level of the foramen of Monro); SP = septum pellucidum (distance from the inner table to the septum pellucidum on the side of the shift).

Apolipoprotein E (apoE) ε4 allele

The presence of this genotype portends a worse prognosis following traumatic brain injury.[28] Furthermore, the incidence of severe brain injury in individuals with the apoE-4 allele greatly exceeds the rate of the allele in the general population.[29] This allele is also a risk factor for Alzheimer's disease (see below) as well as for chronic traumatic encephalopathy (p. 1112) .

67.6 Late complications from traumatic brain injury

67.6.1 General information

Long term complications include:

1. posttraumatic seizures (p. 505)
2. communicating hydrocephalus: incidence ≈ 3.9% of severe head injuries
3. posttraumatic syndrome (or postconcussive syndrome): see below
4. hypogonadotropic hypogonadism (p. 1014) [30]
5. chronic traumatic encephalopathy (p. 1112)
6. Alzheimer's disease (AD): head injury (especially if severe) promotes the deposition of amyloid proteins, especially in individuals possessing the apolipoprotein E (apoE) ε4 allele,[29] which may be related to the development of AD[31,32,33]

67.6.2 Postconcussive syndrome

General information

Variously defined collection of symptoms (see below) that is usually considered as a possible sequelae to minor head trauma (although some of these features can certainly be seen following more serious head trauma). Loss of consciousness is *not* a prerequisite to the development of the syndrome.

Controversy exists over the relative contribution of actual organic dysfunction vs. psychological factors (including conversion reaction, secondary gain which may be for attention, financial reward, drug seeking…). Furthermore, the presence of some of these symptoms can undoubtedly lead to the development of others (e.g., headache can cause difficulty concentrating and thus poor job performance and thence depression).

Presentation

A paradox has been noted by clinicians that the complaints following minor head injury seem out of proportion when considered in the context of the frequency of complaints after serious head injury. It has also been noted that patients with early posttraumatic complaints generally improve with time, whereas the late development of symptoms is often associated with a more protracted and fulminant course.

Symptoms commonly considered part of this syndrome include the following (with headache, dizziness and memory difficulties being the most frequent):

1. somatic
   a) headache
   b) dizziness or light-headedness
   c) visual disturbances: blurring is a common complaint
   d) anosmia
   e) hearing difficulties: tinnitus, reduced auditory acuity
   f) intolerance to light (photophobia) and/or loud (or even moderate) noise (phonophobia)
   g) balance difficulties
2. cognitive
   a) difficulty concentrating
   b) dementia: more common with multiple brain injuries than with a single concussion (p. 1112)
      - loss of intellectual ability
      - memory problems: usually impairs short-term memory more than long-term
   c) impaired judgment
3. psychosocial
   a) emotional difficulties: including depression, mood swings (emotional lability), euphoria/giddiness, easy irritability, lack of motivation, abulia
   b) personality changes
   c) loss of libido

   d) disruption of sleep/wake cycles, insomnia
   e) easy fatigability
   f) increased rate of job loss and divorce (may be related to any of above)

Virtually any symptom can be ascribed to the condition. Other symptoms that may be described by patients which are generally not included in the definition:

1. fainting (vaso-vagal episodes): may need to rule out posttraumatic seizures, as well as other causes of syncope
2. altered sense of taste
3. dystonia[34]

Treatment

Treatment for symptoms attributed to this syndrome tends to be more supportive and reassuring than anything else. Often times these patients obtain treatment from primary care physicians, neurologists, physiatrists, and/or psychiatrists/psychologists. Neurosurgical involvement in the continuing care for these patients is usually at the discretion of the individual physician based on his or her practice patterns. Recovery follows a highly variable course.

Early follow-up care (consisting mainly of reassurance, providing information and neuropsychological assessment and counselling) was found to reduce post-concussion symptoms at 6 months in patients with posttraumatic amnesia lasting ≥ 1 hour or those who required hospitalization, but had no benefit in those not requiring hospitalization or having amnesia < 1 hr.[35]

Some symptoms may need to be evaluated for possible correctable late complications (seizures, hydrocephalus, CSF leak…). Alves and Jane[36] perform a head CT, MRI, BAER and neuropsychological battery if symptoms after minor head injury persist > 3 months. An EEG may be appropriate in cases where there is a question of seizures. If all studies are negative, "the authors tell the patient (and the lawyer) that there is no objective evidence for disease and that psychiatric evaluation is warranted." Non-correctable abnormalities on these studies prompt reassurance that significant symptoms should subside by 1 year, and that no specific treatment, other than psychological counselling, is helpful.

67.6.3 Chronic traumatic encephalopathy

General information

Often described in retired boxers, chronic traumatic encephalopathy (CTE) encompasses a spectrum of symptoms that range from mild to a severe form AKA dementia pugilistica,[37] or punch drunk syndrome (among others). Symptoms involve motor, cognitive, and psychiatric systems. CTE is distinct from posttraumatic dementia (which may follow a single closed head injury) or from posttraumatic Alzheimer's syndrome. Although generally accepted, not all authorities agree that repeated concussions have any long-term sequelae.[38]

There are some similarities with Alzheimer's disease (AD), including the presence of neurofibrillary tangles having similar microscopic characteristics (the main difference is that they tend to be more superficial in CTE than in AD[39]) and the development of amyloid angiopathy with the attendant risk of intracerebral hemorrhage.[40] EEG changes occur in one-third to one-half of professional boxers (diffuse slowing or low-voltage records).

Neuropathology

Findings include:

1. cerebral and cerebellar atrophy
2. neurofibrillary degeneration of cortical and subcortical areas
3. deposition of β-amyloid protein
   a) forming diffuse amyloid plaques
   b) in a subset of CTE patients this involves the vessel walls giving rise to cerebral amyloid angiopathy

Clinical

Clinical features of CTE are shown in ▶ Table 67.2 [37] and include[37]:

1. cognitive: mental slowing and memory deficits (dementia)
2. personality changes: explosive behavior, morbid jealousy, pathological intoxication with alcohol, and paranoia
3. motor: cerebellar dysfunction, symptoms of Parkinson's disease, pyramidal tract dysfunction

Table 67.2 CTE of boxing[a]

Motor	Cognitive	Psychiatric
Early (≈ 57%)		
dysarthria tremors mild incoordination, especially non-dominant hand	decreased complex attention	emotional lability euphoria/hypomania irritability, suspiciousness ease of aggression & talkativeness
Middle (≈ 17%)		
parkinsonism increased dysarthria, tremors, and incoordination	slowed mental speed mild deficits in memory, attention & executive ability	magnified personality decreased spontaneity paranoid, jealous inappropriate violent outbursts
Late (< 3%)		
pyramidal signs prominent parkinsonism prominent dysarthria, tremors & ataxia	prominent slowness of thought/speech amnesia attention deficits executive dysfunction	cheerful/silly decreased insight paranoid, psychotic disinhibited, violent possible Klüver-Bucy

[a] in professional boxers with ≥ 20 bouts

Grading scales have been devised to rank patients as having probable, possible, and improbable CTE.

The chronic brain injury scale (CBIS) assesses involvement of motor, cognitive, and psychological axes as shown in ▶ Table 67.3.

Table 67.3 Chronic brain injury scale

Grade involvement of each of the following axes separately:	Scoring for each axis:
• motor • cognitive • psychological	• 0 = none • 1 = mild • 2 = moderate • 3 = severe
Sum total points	**Severity**
0	normal
1–2	mild
3–4	moderate
> 4	severe

Risk factors for dementia pugilistica in boxing:

See reference.[37]

- risk increases with length of boxing career, especially > 10 yrs
- age at retirement: risk goes up after age 28 yrs
- number of bouts: especially ≥ 20 (more important than the number of knock-outs)
- boxing style: increased risk among poorer performers, those known as sluggers rather than “scientific” boxers, those known to be hard to knock out or known to take a punch and keep going
- age at examination: long latency causes increased prevalence with age
- and possibly, the number of head blows
- risk increases in patients with the apolipoprotein E (apo E) ε4 allele (as in Alzheimer’s disease) as shown in ▶ Table 67.4
- professional boxers (more risk than amateurs)

Neuro-imaging

The most common finding is cerebral atrophy. A cavum septum pellucidum (CSP) is observed in 13% of boxers.[41] CSP in this setting probably represents an acquired condition[42] and correlates with cerebral atrophy.

Table 67.4 Odds ratio for developing Alzheimer's disease

Head injury	Apo E ε4 allele	Odds ratio
–	–	1
–	+	2
+	–	1
+	+	10

68 Spine Injuries – General Information, Neurologic Assessment, Whiplash and Sports-Related Injuries, Pediatric Spine Injuries

68.1 Introduction

20% of patients with a major spine injury will have a second spinal injury at another level, which may be noncontiguous. These patients often have simultaneous but unrelated injuries (e.g., chest trauma, TBI…). Injuries directly associated with spinal cord injuries include arterial dissections (carotid and/or vertebral arteries).

68.2 Terminology

68.2.1 Spinal stability

Many definitions have been proposed. A conceptual definition of clinical stability from White and Panjabi[1]: the ability of the spine under physiologic loads to limit displacement so as to prevent injury or irritation of the spinal cord and nerve roots (including cauda equina), and to prevent incapacitating deformity or pain due to structural changes.

Biomechanical stability refers to the ability of the spine ex vivo to resist forces.

Predicting spinal stability is often difficult, and to this end various models have been developed, none of which is perfect. See models of stability for cervical spine injuries (p. 1182) and thoracolumbar fractures (p. 1200).

68.2.2 Level of injury

There is disagreement over what should be defined as “the level” of a spinal cord injury. Some define the “level” of a spinal cord injury as the lowest level of completely *normal* function (thus a patient would be termed a C5 quadriplegic even with minor C6 motor function). However, most sources define the “level” as the most caudal segment with motor function that is at least 3 out of 5 and if pain and temperature sensation is present.

68.2.3 Completeness of lesion

Categorization is important for treatment decisions and prognostication.

Incomplete lesion

Definition: any residual motor or sensory function more than 3 segments below the level of the injury.[2] Look for signs of preserved long-tract function.

Signs of incomplete lesion:

1. sensation (including position sense) or voluntary movement in the LEs in the presence of a cervical or thoracic spinal cord injury
2. “sacral sparing”: preserved sensation around the anus, voluntary rectal sphincter contraction, or voluntary toe flexion
3. an injury does *not* qualify as incomplete with preserved sacral reflexes alone (e.g., bulbocavernosus)

Types of incomplete spinal cord injury:

1. central cord syndrome (p. 1132)
2. Brown-Séquard syndrome (cord hemisection) (p. 1135)
3. anterior cord syndrome (p. 1135)
4. posterior cord syndrome (p. 1136): rare

Complete lesion

No preservation of any motor and/or sensory function more than 3 segments below the level of the injury in the absence of spinal shock (see below). About 3% of patients with complete injuries on initial exam will develop some recovery within 24 hours. Recovery is essentially zero if the spinal cord injury remains complete beyond 72 hours.

Spinal shock

This term is often used in two completely different senses:

- 1st SENSE: hypotension (shock) that follows spinal cord injury (SBP usually ≈ 80 mm Hg). See Hypotension (p. 1139) for treatment. Caused by multiple factors:
  a) interruption of sympathetics: implies spinal cord injury above T1
    - loss of vasoconstrictors → vasodilatation (loss of vascular tone) below the level of injury
    - leaves parasympathetics relatively unopposed causing *bradycardia*
  b) loss of muscle tone due to skeletal muscle paralysis below level of injury results in venous pooling and thus a relative hypovolemia
  c) blood loss from associated wounds → true hypovolemia
- 2nd SENSE: transient loss of all neurologic function (including segmental and polysynaptic reflex activity and autonomic function) below the level of the SCI[3,4] → flaccid paralysis and areflexia
  a) duration: may abate in as little as 72 hours, but typically persists 1–2 weeks, occasionally several months
  b) accompanied by loss of the bulbocavernosus reflex
  c) spinal cord reflexes immediately above the injury may also be depressed on the basis of the Schiff-Sherrington phenomenon (primarily described in animal models)
  d) when spinal shock resolves, there will be spasticity below the level of the lesion and return of the bulbocavernosus reflex
  e) a poor prognostic sign

68.3 Whiplash-associated disorders

68.3.1 General information

"Whiplash" was initially a lay term, which is currently defined as a traumatic injury to the soft tissue structures in the region of the cervical spine (including: cervical muscles, ligaments, intervertebral discs, facet joints…) due to hyperflexion, hyperextension, or rotational injury to the neck in the absence of fractures, dislocations, or intervertebral disc herniation.[5] It is the most common non-fatal automobile injury.[6] Symptoms may start immediately, but more commonly are delayed several hours or days. In addition to symptoms related to the cervical spine, common associated complaints include headaches, cognitive impairment, and low back pain.

68.3.2 Clinical grading

A proposed clinical classification system of WAD is shown in ▶ Table 68.1.[7]

Table 68.1 Clinical grading of WAD severity

Grade		Description
	0	no complaints, no signs[a]
Whiplash	1	neck pain or stiffness or tenderness, no signs
	2	above symptoms with reduced range of motion or point tenderness
	3	above symptoms with weakness, sensory deficit, or absent deep tendon reflexes
	4	above symptoms with fracture or dislocation[a]

[a]the definition of whiplash excludes these patients[5]

68.3.3 Evaluation and treatment

A consensus[8] regarding diagnosis and management of these injuries is shown in ▶ Table 68.2 and ▶ Table 68.3. Keep in mind that conditions such as occipital neuralgia may occasionally follow whiplash-type injuries and should be treated appropriately (▶ Table 68.3).

Table 68.2 Evaluation of WAD

Grade 1: patients with normal mental status and physical exam do not require plain radiographs on presentation
Grade 2 & 3 patients: C-spine X-rays, possibly with flexion-extension views. Special imaging studies (MRI, CT, myelography…) are not indicated
Grade 3 & 4: these patients should be managed as suspected spinal cord injury; see Initial management of spinal cord injury (p. 1138) and sections that follow

Table 68.3 Treatment of WAD[8][a]

Whiplash is usually a benign condition requiring little treatment and usually resolves in days to a few weeks in most cases.

Recommendation	**Grade**		
	1	2	3
Range of motion exercises	should be started immediately for all		
Encourage early return to regular activities	immediately	ASAP	
Cervical collars and rest[b]	no	not for > 72 hrs	not for > 96 hrs
Passive modality therapies: heat, ice, massage, TENS, ultrasound, relaxation techniques, acupuncture, and work alteration	no	optional if symptoms last > 3 wks	
Medications: optional use of NSAIDs and non-narcotic analgesics? (recommended for ≤ 3 wks)	no	yes	yes. Limited narcotics may also occasionally be needed
Surgery	no	no	only for progressive neurologic deficit or persisting arm pain

✖ ***Not*** recommended: cervical pillows and soft collars, bed rest, spray and stretch exercises, muscle relaxant medication, TENS, reflexology, magnetic necklaces, herbal remedies, homeopathy, OTC medications (except NSAIDs, see above), and intra-articular, intrathecal, or trigger point steroid injections

[a] excluding patients with fractures, dislocations, or spinal cord injuries

[b] soft foam collars are generally discouraged; if they are to be used, the narrow part should be placed in front to avoid neck extension[5]

68.3.4 Outcome

In a study of 117 patients < 56 years of age having WAD due to automobile accidents (excluding those with cervical fractures, dislocations, or injuries elsewhere in the body) conducted in Switzerland[9] (where all medical costs were paid by the state and there was no opportunity for litigation and no compensation for pain and suffering, although there was the possibility of permanent disability), the recovery rate was as shown in ▶ Table 68.4. Of the 21 patients with continued symptoms at 2 yrs, only 5 were restricted with respect to work (3 reduced to part-time work, 2 on disability). Patients with persistent symptoms were older, had more varied complaints on initial exam, had a more rotated or inclined head position at the time of impact, had a higher incidence of pretraumatic headaches, and had a higher incidence of certain pre-existing findings (such as radiologic evidence of cervical osteoarthritis). The amount of damage to the automobile and the speed of the cars had little relationship to the degree of injury, and outcome was not influenced by gender, vocation, or psychological factors.

Table 68.4 Recovery of patients with WAD

Time (mos)	**Percent recovered**
3	56%
6	70%
12	76%
24	82%

68.4 Pediatric spine injuries

68.4.1 General information

Key concepts

- until age ≈ 16, spinal cord injury is relatively infrequent
- ligamentous injuries are more common than actual fractures due to flexibility of ligamentous
- spine/spinal cord injuries that are somewhat unique to the pediatric population
  a) atlantooccipital dislocation (AOD) (p. 1153): a retroclival hematoma should raise the index of suspicion for AOD
  b) SCIWORA (p. 1196) (spinal cord injury without radiographic abnormality)
  c) synchondrosis fractures: os odontoideum (p. 1175), C2 synchondrosis
  d) atlantoaxial rotatory fixation/subluxation (p. 1158)
- when AOD is a consideration, cervical CT is the imaging modality of choice to measure the condyle-C1 interval (CCI)
- most stable fractures and ligamentous injuries may be treated nonsurgically. C2 synchondrosis fractures are ususally managed with halo traction
- surgical challenges include: finding hardware small enough for young children, the small size of C-spine lateral masses, and difficulty thoroughly removing disc material and cartilage

Spinal cord injury is fairly uncommon in children; the ratio of head injuries to spinal cord injuries is ≈ 30:1 in pediatrics. Only ≈ 5% of spinal cord injuries occur in children. Due to ligamentous laxity together with a high head-to-body weight ratio, immaturity of paraspinal muscles and the underdeveloped uncinate processes, these tend to involve ligamentous rather than bony injuries (e.g., SCIWORA (p. 1196)). There is also the potential for physeal (growth plate) separation in young children, which may have good potential to heal. The cervical spine is the most vulnerable segment (with subaxial injuries being fairly uncommon), with 42% of injuries occurring here, 31% thoracic, and 27% lumbar. The fatality rate is higher with pediatric spine injuries than with adults (opposite to the situation with head injury), with the cause of death more often related to other severe injuries than to the spinal injury.[10]

68.4.2 Pediatric cervical spine injuries and mimics

General information

See pediatric C-spine anatomy (p. 224). In the age group ≤ 9 yrs, 67% of cervical spine injuries occur in the upper 3 segments of the cervical spine (occiput-C2).[11]

Synchondroses

Normal synchondroses (p. 226) may be mistaken for fractures, especially the dentocentral synchondrosis of the axis (p. 224) which may be mistaken for an odontoid fracture. Conversely, synchondroses are biomechanically weak links and actual fractures may occur through them (▶ Fig. 68.1).[12,13]

C2 is the most common vertebra injured in children.

▶ **Odontoid epiphysiolysis.** A fracture through the dentocentral synchondrosis (much of the literature says neurocentral synchondrosis, but I believe that is incorrect). Mimics an odontoid type II fracture. 23% will develop neurologic deficit, and in 53% of these the SCI level occurs lower at the cervicothoracic junction.[14] Recommended treatment for fractures through synchondroses: the tendency for synchondroses to fuse suggests that emergency reduction followed by external immobilization should be attempted. For C2, a halo is recommended, with 80–90% success rate.[12,14] Internal immobilization/fusion should be reserved for persistent instability[13] after 3–6 months.[14]

Evaluation

General information

Practice guidelines for diagnostic workup are shown below (see Practice guideline: Evaluation of pediatric C-spine injuries (p. 1122)).

Retroclival hematoma (p. 1102) on imaging should prompt immobilization and evaluation for atlantooccipital dislocation (AOD).

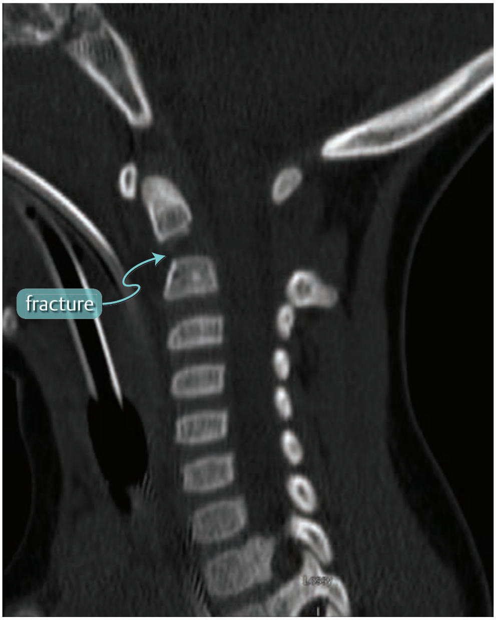

Fig. 68.1 Fracture through C2 dentocentral synchondrosis (odontoid epiphysiolysis).
Sagittal cervical CT in 23-month-old injured in motor vehicle crash.
Note anterior angulation of the odontoid process and several mm of separation from the main C2 vertebral body.

Practice guideline: Evaluation of pediatric C-spine injuries

Level I[15]

- Use CT to assess the condyle-C1 interval (CCI) (p. 1154) (AKA atlantooccipital interval) for pediatric patients with potential atlantooccipital dislocation (AOD)

Level II[15]:

- Do not perform C-spine imaging in children > 3 years of age with trauma who are:
    - alert
    - neurologically intact
    - without posterior midline cervical tenderness (with no distracting pain)
    - not hypotensive without explanation
    - not intoxicated
- Do not perform C-spine imaging in children < 3 years of age with trauma who meet all of the following conditions:
    - have a GCS > 13
    - are neurologically intact
    - have no cervical midline tenderness (without distracting injury)
    - are not intoxicated
    - do not have unexplained hypotension
    - were not in a motor vehicle collision, a fall > 10 feet, or non-accidental trauma (NAT) as the known or suspected mechanism of injury
- Obtain cervical spine X-rays or high-resolution cervical CT in pediatric trauma victims who do not meet either set of criteria above
- Obtain 3-position CT with C1–2 motion analysis to confirm and classify the diagnosis for children suspected of having atlantoaxial rotatory fixation (AARF)

Pseudospread of the atlas

Pseudospread of the atlas is defined as > 2 mm total overlap of the two C1 lateral masses on C2 on AP open-mouth view.[16] This could be misdiagnosed as a *Jefferson fracture* (p. 1162), which rarely occurs prior to the teen-ages (owing to lower weight of children, more flexible necks, increased plasticity of skull, and shock absorbing synchondroses of C1).

Pseudospread is probably a result of disproportionate growth of the atlas on the axis. It is present in most children 3 mos to 4 yrs of age. Prevalence is 91–100% during the second year of life. Youngest example at 3 mos, oldest at 5.75 yrs. Normal total offset is typically 2 mm during the first year, 4 mm during the second, 6 mm during the third, and decreasing thereafter. The maximum is 8 mm. Trauma is not a contributing factor.

Neck rotation can also sometimes simulate the appearance of a Jefferson fracture.

When suspicion of a Jefferson fracture is high: thin cut CT scan parallel to and through C1 can resolve the issue of whether or not there is a fracture.

Pseudosubluxation

Anterior displacement and/or significant angulation, usually of C2 (axis) on C3 (▶ Fig. 68.2) (occasionally C3 on C4) on lateral C-spine X-rays or sagittal imaging (CT or MRI) that may occur normally in children (up to age 10 yrs, sometimes persisting up to age 14[17]). When identified after trauma, this may be misinterpreted as a traumatic injury. Fractures and dislocations are unusual in children, and when they do occur, they resemble those in adults.

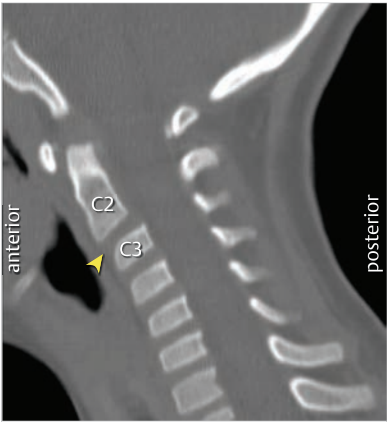

Fig. 68.2 Pseudosubluxation of C2 anteriorly on C3 (*yellow arrowhead*).
Image: sagittal cervical CT scan bone window in a 4-year-old girl.

Physiology: flexion and extension are initially centered at C2–3, this gradually moves down to C4–5 or C5–6 usually by age 10 yrs. C2 normally moves forward on C3 up to 2–3 mm in peds.[18] Forward displacement on neck flexion may be exacerbated by paraspinal spasm at lower levels.[19] It does not represent pathological instability.

10 cases reported between ages 4–6 yrs[20]: pain was not uncommon. In each case, either the head or neck was flexed (sometimes minimally); the pseudosubluxation corrected when X-ray was repeated with head in true neutral position. However, this does not rule out instability.

True subluxation may occur with:

1. fractures (e.g., hangman's fracture (p. 1165)) which allow the C2 VB to move forward without a corresponding displacement of the posterior elements of C2. This may be suspected on plain X-rays with C2-3 subluxation when the base of the C2 spinous process is 1.5 mm posterior to the posterior cervical line of Swischuk (▶ Fig. 12.1),[21] and is assumed to be present when ≥ 2 mm posterior.[17,21] CT scan is diagnostic
2. injury to the C2-3 disc and posterior elements: may be demonstrable on STIR MRI (p. 241)

Treatment

Practice guideline: Treatment of pediatric C-spine injuries

Level III[15]:

- children < 8 yrs of age: when restrained, immobilize with thoracic elevation or an occipital recess (allows more neutral alignment due to the relatively large head)
- children < 7 yrs of age with injuries of the C2 synchondrosis (p. 226): closed reduction and halo immobilization
- patients with atlantoaxial rotatory subluxation/fixation (AARF):
  - acute AARF (< 4 weeks duration) that does not reduce spontaneously: reduction with manipulation or halter traction
  - chronic AARF (> 4 weeks duration): reduction with halter or tong/halo traction
  - recurrent or irreducible AARF: internal fixation and fusion
- for isolated cervical spine ligamentous injuries and unstable or irreducible fractures of dislocations with associated deformity: consider primary operative treatment
- for cervical spine injuries that fail non-operative management: operative treatment

Assessment tools for spinal stability used in adults have not been validated in the pediatric population.

68.5 Cervical bracing

68.5.1 Soft collars

Soft (sponge rubber) collar: does not immobilize the cervical spine to any significant degree. Its function is primarily to remind the patient to reduce neck movements.

68.5.2 Rigid cervical collars

Inadequate for stabilizing upper and mid-cervical spine and for preventing rotation.

Common rigid collars:

- Miami J collar & Aspen collar: have removable pads
- Philadelphia collar: no removable pads. Feels hotter to wear

68.5.3 Poster braces

Distinguished from cervicothoracic orthoses (see below) by the lack of straps under the axilla. Includes the four poster brace. Generally good for preventing flexion at midcervical levels.

68.5.4 Cervicothoracic orthoses

Cervicothoracic orthoses (CTO) incorporate some form of body vest to immobilize the cervical spine. The following are presented in increasing degree of immobilization.

Guilford brace: essentially a ring around the occiput and chin connected by two posts to anterior and posterior thoracic pads.

SOMI brace: acronym for Sternal Occipital Mandibular Immobilizer. Good for bracing against flexion (especially upper cervical spine). Inadequate for hyper-extension type injuries because of weak occipital support. Has special forehead attachment to allow patient to eat comfortably without mandibular support.

"Yale brace": a sort of extended Philadelphia collar. The most effective CTO for bracing against flexion-extension and rotation. Major shortcoming is poor prevention of lateral bending (only ≈ 50% reduced).

68.5.5 Halo-vest brace

Can immobilize the upper or lower cervical spine, not very good for mid-cervical spine (due to snaking of the midcervical spine). Unable to provide adequate distraction support following vertebral body resection when patient assumes upright position (i.e., it is *not* a portable cervical traction device). Overall reduction of flexion/extension as well as lateral bending is ≈ 90–95%, rotation is reduced by 98%. See placement (p. 1147).

68.6 Follow-up schedule

After initial management (surgical or nonsurgical) of cervical spine problems (stable or unstable), the follow-up schedule shown in ▶ Table 68.5 is suggested to permit recognition of problems in time for treatment[1] (start with 3 weeks and keep doubling the interval to 1 year).

Table 68.5 Sample follow-up cervical spine clinic visit schedule

Time post-op	Agenda
7–10 days	(for post-op patients only) wound check, D/C sutures/staples if used
4–6 weeks	AP & lateral C-spine X-ray in brace (no flexion/extension) to rule out instability or progression of fracture(s)
10–12 weeks	• AP & lateral C-spine X-rays with flexion/extension views out of brace • if X-rays show no instability or progression of fracture(s) and patient is doing well, begin weaning brace
6 months	• AP & lateral C-spine X-rays with flexion/extension views • some surgeons release patients at this time if they are doing well
1 year (optional)	• AP & lateral C-spine X-rays with flexion/extension views • release patient if they are doing well

68.7 Sports-related cervical spine injuries

68.7.1 General information

Any of the spine injuries described in this book can be sports-related. This section considers some injuries peculiar to sports.

Bailes et al[22] classified sports-related spinal cord injuries (SCI) as shown in ▶ Table 68.6. Type I injures may be complete or may have features of any of the incomplete SCI syndromes (often in mixed or partial forms). Type II injuries include spinal concussion, spinal neuropraxia (see below), and the burning hands syndrome (see below), all in the absence of radiographic abnormalities and all with complete resolution of symptoms. Patients should be carefully evaluated, and return to competition should not be allowed in the presence of neurologic deficit, radiographically demonstrated injury, certain congenital C-spine abnormalities, and possibly for "repeat offenders" (p. 1126). Type III injuries are the most common. Unstable injuries should be treated appropriately (p. 1194).

Table 68.6 Sports-related spinal cord injuries

Type	Description
I	permanent SCI
II	transient SCI without radiographic abnormality
III	radiologic abnormality without neurologic deficit

68.7.2 Football-related cervical spine injuries

General information

✖ Football players with suspected C-spine injury should not have their helmet removed in the field (p. 1138).

Terminology

The following terms probably originated as locker-room jargon for various cervical spine-related injuries usually sustained in playing football. Medical definitions have subsequently been retrofitted to them. As a result, the precise definitions may not be uniformly agreed upon. Although the semantics may differ, it is more important from a diagnostic and therapeutic standpoint to distinguish nerve root injuries, brachial plexus injuries, and spinal cord injuries.

1. cervical cord neuropraxia[23] (CCN): sensory changes that may involve numbness, tingling or burning. May or may not be associated with motor symptoms of weakness or complete paralysis. Typically lasts < 15 mins (although may persist up to 48 hrs), involves all 4 extremities in 80% of cases. Narrowing of the sagittal diameter of the cervical spinal canal is felt to be a contributory

factor. With resumption of contact activities, recurrence rate is ≈ 56%, with higher risks of recurrence among those with narrower canal diameters. Evaluation should include cervical MRI. Torg[23] feels that uncomplicated cases of CCN (no spinal instability and no MRI evidence of cord defect or edema) have a low risk of permanent injury and does not recommend activity restrictions

2. "stinger" or "burner": distinct from the burning hands syndrome. Unilateral, burning dysesthetic pain radiating down one arm from the shoulder, sometimes associated with weakness involving the C5 or C6 nerve roots. Usually follows a tackle. May result from downward traction on the upper trunk of the brachial plexus (when the shoulder is forcefully depressed with the neck flexed to the contralateral side) or by direct nerve root compression in the neural foramina (not an SCI)
3. burning hands syndrome[24]: similar to a stinger, but bilateral. Probably represents an *SCI*; possibly a mild variant of a central cord syndrome (p. 1132)
4. other neurologic injuries include: vascular injury to carotid or vertebral arteries. Usually related to intimal dissection (p. 1220) following a direct blow to the neck or by extreme movements. Symptoms are those of a TIA or stroke

Spear tackler's spine

Rule changes in 1976 banned spearing (the practice of using the football helmet as a battering ram to tackle an opponent) and resulted in a reduction of the number of football-related occurrences of cervical spine fractures and quadriplegia.[25]

Four characteristics of spear tackler's spine:

1. cervical spinal stenosis
2. loss of normal cervical lordosis: as a result, the stress of axial loading is more likely to be imparted to the vertebral bodies, rather than being absorbed by the cervical musculature and ligaments, increasing the risk of burst fractures and quadriplegia
3. evidence of pre-existing traumatic abnormalities
4. documented spear tackler's technique

Suggested management:

The athlete is removed from competition until the cervical lordosis returns and the player learns to use other tackling techniques. This tackling technique has been banned since 1976.

68.7.3 Return to play and pre-participation guidelines

Return to play (RTP) and pre-participation evaluation guidelines related to the cervical spine are shown in ▶ Table 68.7 (modified[26]). These are just guidelines, and do not ensure safety. Clinical judgment must always be employed.

Table 68.7 C-spine-related contraindications for participation in contact sports[a]

Condition[b]			**C.I.[c]**
Congenital[d]			
1.	odontoid abnormalities (serious injury may result from atlanto-axial instability)		
	a.	complete aplasia (rare)	absolute
	b.	hypoplasia (seen in conjunction with achondroplasia and spondyloepiphyseal dysplasia)	absolute
	c.	os odontoideum (probably of traumatic origin)	absolute
2.	atlantooccipital fusion (partial or complete fusion of atlas to occiput): sudden onset of symptoms & sudden death have been reported		absolute
3.	Klippel-Feil anomaly (congenital fusion of 2 or more cervical vertebrae)[e]		
	a.	Type I: mass fusion of C-spine to upper T-spine	absolute
	b.	Type II: fusion of only 1 or 2 interspaces	
		● associated with limited ROM, occipitocervical anomalies, instability, disc disease or degenerative changes	absolute
		● associated with full ROM and none of the above	none

(continued)

Table 68.7 continued

Condition[b]			C.I.[c]
Acquired			
1.	cervical spinal stenosis[f]		
	a.	asymptomatic	none
	b.	with one episode of cord neuropraxia	relative
	c.	cord neuropraxia + MRI evidence of cord defect or edema	absolute
	d.	cord neuropraxia + ligamentous instability, symptoms or neurologic findings > 36 hrs, or multiple episodes	absolute
2.	spear tackler's spine (see text)		absolute
3.	spina bifida occulta: rare, incidental X-ray finding		none
Posttraumatic upper cervical spine			
1.	atlantoaxial instability (ADI > 3 mm adults, > 4 mm peds)		absolute
2.	atlantoaxial rotatory fixation (may be associated with disruption of transverse ligament)		absolute
3.	fractures		
	a.	healed, pain-free, full ROM, & no neurologic findings with any of the following fractures: nondisplaced Jefferson fracture; odontoid fracture; or lateral mass fracture of axis	none
	b.	all others	absolute
4.	post-surgical atlantoaxial fusion		absolute
Posttraumatic subaxial cervical spine			
1.	ligamentous injuries: > 3.5 mm subluxation, or $> 11°$ angulation on flexion-extension views		absolute
2.	fractures		
	a.	healed, stable fractures listed here with normal exam: VB compression fracture without posterior involvement; spinous process fractures	none
	b.	VB fractures with sagittal component or posterior bony or ligamentous involvement	absolute
	c.	comminuted fracture with displacement into spinal canal	absolute
	d.	lateral mass fracture producing facet incongruity	absolute
3.	intervertebral disc injury		
	a.	healed herniated disc treated conservatively	none
	b.	S/P ACDF with solid fusion, no symptoms, normal exam, and full pain-free ROM	none
	c.	chronic herniated disc with pain, neuro findings or ↓ ROM, or acute herniated disc	absolute
4.	S/P fusion		
	a.	stable one-level fusion	none
	b.	stable two-level fusion	relative
	c.	fusion > 2 levels	absolute

[a] organized contact sports includes[26]: boxing, football, ice hockey, lacrosse, rugby & wrestling

[b] see also cranial-related (and craniocervical) conditions (p. 1308) (e.g., Chiari I malformation…)

[c] C.I. = contraindications, classified as absolute, relative (i.e., uncertain) or none

[d] congenital abnormalities may have particular relevance to Special Olympics

[e] NB: Klippel-Feil may be associated with abnormalities in other organ systems (e.g., cardiac) which may impact on participation in contact sports (p. 289)

[f] Pavlov ratio (p. 1302) has a low positive predictive value for injuries in contact sports and is therefore not a useful screening test (i.e., an asymptomatic Pavlov ratio < 0.8 is not a contraindication to participation)

68.8 Neurological assessment

68.8.1 General information

Evaluation of the level of the lesion requires familiarity with the following concepts about the relationship between the bony spinal canal and the spinal cord and nerves (▶ Fig. 68.3).

1. since there are 8 pairs of cervical nerves and only 7 cervical vertebra
   a) cervical nerves 1 through 7 exit *above* the pedicles of their like-numbered vertebra
   b) C8 exits below the C7 pedicle
   c) thoracic, lumbar, and sacral nerves exit *below* the pedicles of their like-numbered vertebra

Fig. 68.3 Relationship between spinal cord, nerve roots, and bony spine.
The conus medullaris in the adult lies at about L1 or L2 of the spine (see text).
The lower extent of the thecal sac is typically around S2.
The C1 through C7 nerve roots exit *above* the pedicles of their like-numbered vertebra. Nerve roots of T1 and lower exit below the pedicles of their like-numbered vertebra.

2. due to disproportionately greater growth of the spinal column than the spinal cord during development, the following relationships of the spinal *cord* to the vertebral column exist:
   a) to determine which segment of the spinal cord underlies a given vertebra:
      - from T2 through T10: add 2 to the number of the spinous process
      - for T11, T12 and L1, remember that these overlie the 11 lowest spinal segments (L1 through L5, S1 through S5, and Coxygeal-1)
   b) the mean position of the conus medullaris (the lowest extent of the spinal cord) is attained during the first few months of life and doesn't change.[27] It is at the lower third of the L1 VB on MRI in adults (range: middle third of T12 to upper third of L3)[28]

68.8.2 Motor level assessment

General information

▶ Table 68.8 and ▶ Table 68.9 are for rapid assessment (see ▶ Table 30.5 and ▶ Table 30.7 for detailed tables of motor innervation).

Table 68.8 Key muscles for motor level classification (EXTREMITIES)

RIGHT grade	Segment	Muscle	Action to test	LEFT grade
0–5	C5	biceps	flex elbow	**0–5**
0–5	C6	wrist extensors	cock up wrist	**0–5**
0–5	C7	triceps	extend elbow	**0–5**
0–5	C8	flexor digitorum profundus	flex middle distal phalanx	**0–5**
0–5	T1	hand intrinsics	abduct little finger	**0–5**
0–5	L2	iliopsoas	flex hip	**0–5**
0–5	L3	quadriceps	straighten knee	**0–5**
0–5	L4	tibialis anterior	dorsiflex foot	**0–5**
0–5	L5	EHL	dorsiflex big toe	**0–5**
0–5	S1	gastrocnemius	plantarflex foot	**0–5**
50	← TOTAL POSSIBLE POINTS →			**50**
GRAND TOTAL: 100				

Table 68.9 Axial muscle evaluation[31]

Level	Muscle	Action to test
C4	diaphragm	tidal volume (TV), FEV1, and vital capacity (VC)
T2–9 T9–10 T11–12	intercostals upper abdominals lower abdominals	use sensory level, abdominal reflexes, & Beevor's sign

ASIA (American Spinal Injury Association) motor scoring system

A system[29,30] that may be rapidly applied to grade 10 key motor segments using the MRC Grading Scale (▶ Table 30.2) from 0–5 on the left and the right, for a total score of 100 possible points (see ▶ Table 68.8). NB: most muscles receive innervation from two adjacent spinal levels, the levels listed in ▶ Table 68.8 are the *lower* of the two. The standard considers a segment intact if the motor grade is fair (≥ 3). For additional information, see www.asia-spinalinjury.org.

More detailed motor evaluation

See ▶ Table 68.10.

Table 68.10 Skeletal muscles and their major spinal innervation (major contributing segment is shown in boldface)

Segment	Muscle	Action to test	Reflex
C1–4	neck muscles		
C3, 4, 5	diaphragm	inspiration, TV, FEV1, VC	
C5, 6	deltoid	abduct arm > 90°	
C5, 6	biceps	elbow flexion	biceps
C6, 7	extensor carpi radialis	wrist extension	supinator
C7, 8	triceps, extensor digitorum	elbow and finger extension	triceps
C8, T1	flexor digitorum profundus	grasp (flex distal phalanges)	
C8, T1	hand intrinsics	abduct little finger, adduct thumb	
T2–9	intercostals[a]		
T9,10	upper abdominals[a]	Beevor's sign[b]	abdominal cutaneous reflex[c]
T11, 12	lower abdominals[a]		
L2, 3	iliopsoas, adductors	hip flexion	cremasteric reflex[d]
L3, 4	quadriceps	knee extension	infrapatellar (knee jerk)
L4, 5	medial hamstrings, tibialis anterior	ankle dorsiflexion	medial hamstrings
L5, S1	lateral hamstrings, posterior tibialis, peroneals	knee flexion	
L5, S1	extensor digitorum, EHL	great toe extension	
S1, 2	gastrocs, soleus	ankle plantarflexion	Achilles (ankle jerk)
S2, 3	flex digitorum, flex hallucis		
S2, 3, 4	bladder, lower bowel, anal sphincter	clamp down during rectal exam	anal cutaneous reflex[e], bulbocavernosus & priapism

[a] also use sensory level to help evaluate these segments

[b] Beevor's sign: used to assess abdominal musculature for level of lesion. Patient lifts head off of bed by flexing neck; if lower abdominal muscles (below ≈ T9) are weaker than upper abdominal musculature, then umbilicus moves cephalad. Not helpful if both upper and lower abdominals are weak

[c] the abdominal cutaneous reflex: scratching one quadrant of abdomen with sharp object causes contraction of underlying abdominal musculature, causing umbilicus to migrate toward that quadrant. Upper abdominal reflex: T8–9. Lower abdominal reflex: T10–12. This is a cortical reflex (i.e., reflex loop ascends to cortex, and then descends to abdominal muscles). The presence of this response indicates an incomplete lesion for cord injuries above the lower thoracic level

[d] cremasteric reflex: L1–2 superficial reflex

[e] **anal-cutaneous reflex**: AKA anal wink. Normal reflex: mild noxious stimulus (e.g., pinprick) applied to skin in region of anus results in involuntary anal contraction. **Bulbocavernosus (BC) reflex**: see section 68.8.5

68.8.3 Sensory level assessment (dermatomes and sensory nerves)

ASIA standards.[29]

28 key points identified in ▶ Table 68.11 are scored separately for pinprick and light touch on the left & right side using the grading scale shown in ▶ Table 68.12, for a maximum possible total of 112 points for pinprick (left & right) and 112 points for light touch (left & right).

NB: regarding the "C4 cape" AKA "bib" region across the upper chest and back: sensory segments "jump" from C4 to T2 with the intervening levels distributed exclusively on the UEs (▶ Fig. 1.16). The location of this transition is not constant from person to person.

68.8.4 Rectal exam

1. external anal sphincter is tested by insertion of the examiner's gloved finger
   a) perceived sensation is recorded as present or absent. Any sensation felt by the patient indicates that the injury is sensory incomplete
   b) record resting sphincter tone and any voluntary sphincter contraction
2. bulbocavernosus (BC) reflex (p. 1130); see also below: Absence suggests the presence of spinal shock, and it may not be possible to declare a suprasacral SCI as complete because there might be spinal shock which could transiently suppress spinal cord function

Table 68.11 Key sensory landmarks

Level	Dermatome
C2	**occipital protuberance**
C3	supraclavicular fossa
C4	top of acromioclavicular joint
C5	Lateral side of antecubital fossa
C6	thumb, dorsal surface, proximal phalanx
C7	middle finger, dorsal surface, proximal phalanx
C8	little finger, dorsal surface, proximal phalanx
T1	medial (ulnar) side of antecubital fossa
T2	apex of axilla
T3	third intercostal space (IS)
T4	fourth IS (nipple line)
T5	fifth IS (midway between T6 & T8)
T6	sixth IS (xiphoid process)
T7	seventh IS (midway between T6 & T8)
T8	eighth IS (midway between T6 & T10)
T9	ninth IS (midway between T8 & T10)
T10	tenth IS (umbilicus)
T11	eleventh IS (midway between T10 & T12)
T12	inguinal ligament at mid-point
L1	half the distance between T12 & L2
L2	mid-anterior thigh
L3	medial femoral condyle
L4	medial malleolus
L5	dorsum of foot at 3rd MTP (metatarsal phalangeal) joint
S1	lateral heel
S2	popliteal fossa in the mid-line
S3	ischial tuberosity
S4–5	perianal area (taken as 1 level)

Table 68.12 Sensory grading scale

Grade	Description
0	absent
1	impaired (partial or altered appreciation)
2	normal
NT	not testable

68.8.5 Bulbocavernosus (BC) reflex

A polysynaptic spinal cord mediated reflex relayed via S2–4 nerve roots. Contraction of anal sphincter in response to squeezing the glans penis in males, or to tugging on the Foley catheter in either sex is a normal response (must be differentiated from the movement of the Foley catheter balloon).

Loss of the bulbocavernosus (BC) reflex can occur with:

1. spinal shock: the BC reflex may be lost with spinal shock as can occur with suprasacral injuries. Reportedly, the return of the BC reflex may be the earliest clinical indicator that spinal shock has subsided
2. injuries involving the cauda equina or conus medullaris

Presence of BC reflex used to be taken as an indication of an incomplete injury, but its presence alone is no longer considered to have a good prognosis for recovery.

68.8.6 Additional sensory exam

The following elements are considered optional but it is recommended that they be graded as absent, impaired, or normal:

1. position sense: test index finger and great toe on both sides
2. awareness of deep pressure/deep pain

68.8.7 ASIA impairment scale

The ASIA impairment scale*[29] is shown in ▶ Table 68.13 (a modified Frankel Neurological Performance scale[32]).

*NB: this scale indicates the completeness of spinal cord injury and is distinct from the other ASIA grading scales; see also motor and sensory scoring (p. 1129).

Table 68.13 ASIA impairment scale

Class	Description
A	complete: no motor or sensory function preserved
B	incomplete: sensory but no motor function preserved below the neurologic level (includes sacral segments S4–5)
C	incomplete: motor function preserved below the neurologic level (more than half of key muscles below the neurologic level have a muscle strength grade < 3)[a]
D	incomplete: motor function preserved below the neurologic level (more than half of key muscles below the neurologic level have a muscle strength grade ≥ 3)
E	normal: sensory & motor function returned to normal

[a] for muscle strength grading, see ▶ Table 30.2

68.9 Spinal cord injuries

68.9.1 Complete spinal cord injuries

See definition of complete vs. incomplete spinal cord injury (p. 1118).

In addition to loss of voluntary movement, sphincter control and sensation below the level of the injury, there may be priapism (p. 1140). Hypotension and bradycardia (p. 1119) (spinal shock) may also present.

68.9.2 Bulbar-cervical dissociation

Occurs as a result of spinal cord injury at or above ≈ C3 (includes SCI from atlantooccipital and atlantoaxial dislocation). Bulbar-cervical dissociation produces immediate pulmonary and, often, cardiac arrest. Death results if CPR is not instituted within minutes. Patients are usually quadriplegic and ventilator dependent (phrenic nerve stimulation may eventually allow independence from ventilator).

68.9.3 Incomplete spinal cord injuries

Central cord syndrome

General information

Key concepts

- disproportionately greater motor deficit in the upper extremities than lower
- usually results from hyperextension injury in the presence of osteophytic spurs
- surgery is often employed for ongoing compression, usually on a non-emergency basis except for rare cases of progressive deterioration

Originally described by Schneider et al[33] in 1954. Central cord syndrome (CCS) is the most common type of incomplete spinal cord injury syndrome. Usually seen following acute hyperextension injury in an older patient with pre-existing acquired stenosis as a result of bony hypertrophy (anterior spurs) and infolding of redundant ligamentum flavum (posteriorly), sometimes superimposed on congenital spinal stenosis. Translational movement of one vertebra on another may also contribute. A blow to the upper face or forehead is often disclosed on history, or is suggested on exam (e.g., lacerations or abrasions to face and/or forehead). This often occurs in relation to a motor vehicle accident or to a forward fall, often while intoxicated. Younger patients may also sustain CCS in sporting injuries; see burning hands syndrome (p. 1711). CCS may occur with or without cervical fracture or dislocation.[34] CCS may be associated with acute traumatic cervical disc herniation. CCS may also occur in rheumatoid arthritis.

Pathomechanics

Traditional dogma was that the centermost region of the spinal cord is a vascular watershed zone which renders it more susceptible to injury from compression or edema, and that the lateral corticospinal tract (CST) was somatotopically organized such that cervical fibers are located more medially than the fibers serving the lower extremities. This anatomical model has been convincingly challenged by Levi and Schwab,[35] who theorize that the proportionally greater effect on the upper extremities is due to the predominance of large-diameter motor axons subserving the upper extremities (especially the highly represented hands which is responsible for human manual dexterity), along with the fact that motor function of the lower extremities can be conveyed via other motor tracts including the rubrospinal and vestibulospinal tracts.

Presentation

The clinical syndrome is somewhat similar to that seen in syringomyelia[33]

1. motor: weakness of upper extremities with lesser effect on lower extremities
2. sensory: varying degrees of disturbance below level of lesion may occur
3. myelopathic findings: sphincter dysfunction (usually urinary retention)

Hyperpathia to noxious and non-noxious stimuli is also common, especially in the proximal portions of the upper extremities, and is often delayed in onset and extremely distressing to the patient.[36] Lhermitte's sign (p. 1712) occurs in ≈ 7% of cases.

Natural history

There is often an initial phase of improvement (characteristically: LEs recover first, bladder function next, UE strength then returns with finger movements last; sensory recovery has no pattern) followed by a plateau phase and then late deterioration.[37] 90% of patients are able to walk with assistance within 5 days.[38] Recovery is usually incomplete, and the amount of recovery is related to the severity of the injury and patient age.[39]

If CCS results from hematomyelia with cord destruction (instead of cord contusion), then there may be extension (upward or downward).

Evaluation

Findings: young patients tend to have disc protrusion, subluxation, dislocation or fractures.[38] Older patients tend to have multi-segmental canal narrowing due to osteophytic bars, discs, and inbuckling of ligamentum flavum.[38]

C-spine X-rays: may demonstrate congenital narrowing of AP diameter of spinal canal, superimposed osteophytic spurs, traumatic fracture-dislocation. Occasionally, AP narrowing alone without spurs may be seen.[34] Plain X-rays will fail to demonstrate canal narrowing due to thickening or inbuckling of ligamentum flavum, hypertrophy of facet joints, and poorly calcified spurs.[34]

Cervical CT scan: also helpful in diagnosing fractures and osteophytic spurs. Not as good as MRI for assessing status of discs, spinal cord, and nerves.

MRI: discloses compromise of anterior spinal canal by discs or osteophytes (when combined with plain C-spine X-rays or CT, it increases the ability to differentiate osteophyte from traumatic disc herniation). Also good for evaluating ligamentum flavum. T2WI may show spinal cord edema acutely,[40] and can detect hematomyelia. MRI is poor for identifying fractures.

Treatment

General information

Key concepts

- there is no role for surgery without ongoing compression or instability
- timing (for patient with ongoing spinal cord compression)
  - emergency surgery: documented *progressive deterioration* should be decompressed ASAP
  - early surgery (≤ 24 hrs) when possible for spinal instability or patients with long tract findings (p. 1149)
  - patients that are improving should be followed and decompression can be done electively (usually within 2–3 weeks) without an arbitrary waiting period

Practice guideline: Acute traumatic central cord injuries

Level III[39,41]

- ICU management of patients with acute traumatic central cord syndrome (ATCCS), especially for those with severe neurologic deficits (because of possible cardiac, pulmonary & BP disturbances)
- medical management to include the following: cardiac, hemodynamic, and respiratory monitoring and maintainence of MAP 85–90 mm Hg (use BP augmentation if necessary) for the 1st week after injury to improve spinal cord perfusion
- early reduction/stabilization of fracture-dislocation injuries
- surgical decompression of the compressed spinal cord, particularly if the compression is focal and anterior. Unresolved: the role of surgery in ATCCS with long segment cord compression or with spinal stenosis without bony injury[41] (see text for details)

Indications & timing of surgery

Surgical indications

1. continued compression of the spinal cord (e.g., by osteophytic spurs) that correlates with the level of deficit with any of the following:
   a) persistent significant motor deficit following a varying period of recovery (see below)
   b) deterioration of function
   c) continued significant dysesthetic pain
2. instability of the spine

Timing of surgery

Background: a perennial point of controversy. Early dogma was that early surgery for this condition is *contraindicated* because it worsened the deficit. In the absence of spinal instability, traditional management consisted of bed rest in a soft collar for ≈ 3–4 weeks, with consideration for surgery after this time, or else gradual mobilization in the same collar for an additional 6 weeks. However, the basis for this recommendation was at least in part derived from an early report of only 8 patients with CCS, 2 of which underwent surgery, with 1 being worse post-op (the operation consisted of laminectomy, opening the dura, sectioning the dentate ligament, and manipulation of the spinal cord in order to inspect the anterior spinal canal).[33]

► **Early surgery.** Early (usually considered < 24 hrs after injury) decompressive surgery (without cord manipulation) appears to be safe[42] in medically stable patients (see section 69.6 for discussion of timing). The strongest indications for *early* surgery for ATCCS are:

- the rare patient who is improving and then deteriorates.[43] However, great restraint must be used in avoiding what would be an inappropriate operation in many patients[44]
- additional presence of long tract findings: i.e., not a pure CCS, but a combination of other types of incomplete SCI

► **"Delayed surgery."** Defined as surgery after 24-26 hours following SCI.

For patients with ATCCS with significant persistent cord compression who consistently fail to progress after an initial period of improvement,[40] surgery is indicated often within 2–3 weeks following the trauma without an arbitrary waiting period. Better results occur with decompression within the first few weeks or months rather than very late (e.g., ≥ 1–2 years).[45 (p 1010)]

Some authorities contend that the worst time to operate on patients is starting 48 hours from the injury and lasting several days to a week due to swelling of the spinal cord which may render it fragile.

Technical considerations of surgery

The most rapid procedure to decompress the cord is often a multi-level laminectomy. This is frequently accompanied by dorsal migration of the spinal cord which may be seen on MRI.[37] With myelopathy, fused patients fare better than those that are just decompressed without fusion. Fusion may be accomplished posteriorly (e.g., with lateral mass screws and rods) at the time of decompression, or anteriorly (e.g., multi-level discectomy, or corpectomy with strut graft and anterior cervical plating) at the same sitting as the laminectomy or staged at a later date.

Prognosis

In patients with cord contusion without hematomyelia, ≈ 50% will recover enough LE strength and sensation to ambulate independently, although typically with significant spasticity. Recovery of UE function is usually not as good, and fine motor control is usually poor. Bowel and bladder control often recover, but bladder spasticity is common. Elderly patients with this condition generally do not fare as well as younger patients, with or without surgical treatment (only 41% over age 50 become ambulatory, versus 97% for younger patients[46]).

Anterior cord syndrome

General information

AKA anterior spinal artery syndrome. Cord infarction in the territory supplied by the anterior spinal artery. Some say this is more common than central cord syndrome.

May result from occlusion of the anterior spinal artery, or from anterior cord compression, e.g., by dislocated bone fragment, or by traumatic herniated disc.

Presentation

1. paraplegia, or (if higher than ≈ C7) quadriplegia
2. dissociated sensory loss below lesion:
   a) loss of pain and temperature sensation (spinothalamic tract lesion)
   b) preserved two-point discrimination, joint position sense, deep pressure sensation (posterior column function)[47]

Evaluation

It is vital to differentiate a non-surgical condition (e.g., anterior spinal artery occlusion) from a surgical one (e.g., anterior bone fragment). This requires one or more of: myelography, CT, or MRI.

Treatment

Surgical intervention is indicated for patients with evidence of cord compression (e.g., by large central disc herniation) or for spinal instability (ligamentous or bony).

Prognosis

The worst prognosis of the incomplete injuries. Only ≈ 10–20% recover functional motor control. Sensation may return enough to help prevent injuries (burns, decubitus ulcers…).

Brown-Séquard syndrome

General information

Spinal cord hemisection. First described in 1849 by Brown-Séquard.[48]

Etiologies

Usually a result of penetrating trauma, it is seen in 2–4% of traumatic spinal cord injuries.[49] Also may occur with radiation myelopathy, cord compression by spinal epidural hematoma, large cervical disc herniation[50,51,52] (rare), spinal cord tumors, spinal AVMs, cervical spondylosis, and spinal cord herniation (p. 1404).

Presentation

Classical findings (rarely found in this pure form):

1. motor: *ipsilateral* weakness below lesion (due to lateral corticospinal tract dysfunction). Neuroanatomical correlate: motor fibers of the lateral corticospinal tract cross at the pyramidal decussation in the medulla
2. dissociated sensory loss
   a) *contralateral* loss of pain and temperature sensation inferior to lesion (lateral spinothalamic tract dysfunction) starting 1-2 levels *below* the lesion. Neuroanatomical correlate: pain & temperature fibers cross and ascend 1-2 levels in the dorsolateral fasciculus (zone of Lissauer) before entering the contralateral lateral spinothalamic tract
   b) *ipsilateral* loss of vibratory and joint position sense and touch and pressure (dorsal column dysfunction) starting *at the level* of the lesion. Neuroanatomical correlate: these fibers are transmitted by the dorsal columns of the spinal cord which ascend uncrossed until they decussate in the medial lemniscus in the medulla
   c) contralateral loss of crude touch due to disruption of the anterior spinothalamic tract. This may be partially mitigated to varying degrees by redundant fibers in the ipsilateral spinotectal tract

Prognosis

This syndrome has the best prognosis of any of the incomplete spinal cord injuries. ≈ 90% of patients with this condition will regain the ability to ambulate independently as well as anal and urinary sphincter control.

Posterior cord syndrome

AKA contusio cervicalis posterior. Relatively rare. Produces pain and paresthesias (often with a burning quality) in the neck, upper arms, and torso. There may be mild paresis of the UEs. Long tract findings are minimal.

69 Management of Spinal Cord Injury

69.1 Spinal trauma management – general information

The major causes of death in spinal cord injury (SCI) are aspiration and shock.[1] Initial survey under ATLS protocol: assessment of airway takes precedence, then breathing, then circulation & control of hemorrhage ("ABC's"). This is followed by a brief neurologic exam.

NB: other injuries (e.g., abdominal injuries) may be masked below the level of SCI.

Any of the following patients should be treated as having an SCI until proven otherwise:

1. all victims of significant trauma
2. trauma patients with loss of consciousness
3. minor trauma victims with complaints referable to the spine (neck or back pain or tenderness) or spinal cord (numbness or tingling in an extremity, weakness, paralysis)
4. associated findings suggestive of SCI include
   a) abdominal breathing
   b) priapism (p. 1140)

Trauma patients are triaged as follows:

1. no history of significant trauma, completely alert, oriented, and free of drug or alcohol intoxication, with no complaints referable to the spine: most may be cleared clinically without the need for C-spine X-rays; see Radiographic evaluation (p. 1141)
2. significant trauma, but no strong evidence of spine or spinal cord injury: the emphasis here is in ruling out a bony lesion and preventing injury
3. patients with neurologic deficit: the emphasis here is to define the skeletal injury and to take steps to prevent further cord injury and loss of function and minimize or reverse the present deficit. The pros and cons of the high-dose methylprednisolone protocol (p. 1140) should be weighed if a neurologic deficit is identified

69.2 Management in the field

1. Spine immobilization prior to and during extrication from vehicle and transport to prevent active or passive movements of the spine.
   a) For possible C-spine injuries in football players, see ▶ Table 69.1 for the National Athletic Trainers' Association (NATA) guidelines for helmet removal. When CPR is necessary it takes precedence. Caution with intubation (see below)
   b) place patient on back-board
   c) sandbags on both sides of the head with a 3 inch strip of adhesive tape from one side of the back-board to the other across the forehead immobilizes the spine as well as a rigid orthosis[2] but allows movement of the jaw and access to the airway
   d) a rigid cervical collar (e.g., Philadelphia collar) may be used to supplement

Table 69.1 NATA helmet removal guidelines[a]

✖ **NB: do not remove the helmet in the field.**
• most injuries can be visualized with the helmet in place • neurological exam can be done with the helmet in place • the patient may be immobilized on a spine board with the helmet in place • the facemask can be removed with special tools to access the airway • hyperextension must be avoided following removal of the helmet and shoulder pads
In a controlled setting (usually after X-rays) the helmet and shoulder-pads are removed together as a unit to avoid neck flexion or extension
Possible indications for removal of helmet
• face mask cannot be removed in a reasonable amount of time • airway cannot be established even with face mask removed • life threatening hemorrhage under the helmet that can be controlled only by removal • helmet & strap do not hold head securely so that immobilizing the helmet does not adequately immobilize the spine (e.g., poor fitting or damaged helmet) • helmet prevents immobilization for transportation in an appropriate position • certain situations where the patient is unstable (M.D. decision)

[a] for more details, see http://www.nata.org

2. maintain blood pressure, see below under Hypotension (p. 1139)
   a) pressors treat the underlying problem (SCI is essentially a traumatic sympathectomy). Dopamine is the agent of choice, and is preferred over fluids (except as necessary to replace losses); see Cardiovascular agents for shock (p. 133) for pressors. ✖ Avoid phenylephrine (see below)
   b) fluids as necessary to replace losses
   c) military anti-shock trousers (MAST): immobilizes lower spine, compensates for lost muscle tone in cord injuries (prevents venous pooling)
3. maintain oxygenation (adequate FIO_2 and adequate ventilation)
   a) if no indication for intubation: use NC or face mask
   b) intubation: may be required for airway compromise or for hypopnea. In SCI, hypopnea may be due to: paralyzed intercostal muscles, paralysis of diaphragm (phrenic nerve = C3, 4 & 5). Hypopnea may also be due to depressed LOC in TBI
   c) caution with intubation with uncleared C-spine
      - use chin lift (not jaw thrust) without neck extension
      - nasotracheal intubation may avoid movement of C-spine but patient must have spontaneous respirations
      - avoided tracheostomy or cricothyroidotomy if possible (may compromise later anterior cervical spine surgical approaches)
4. brief *motor* exam to identify possible deficits (also to document delayed deterioration); ask patient to:
   a) move arms
   b) move hands
   c) move legs
   d) move toes

69.3 Management in the hospital

69.3.1 Stabilization and initial evaluation

1. immobilization: maintain backboard/head-strap (see above) to facilitate transfers to CT table, etc. Log-roll patient to turn. Once studies are completed, remove patient from backboard ASAP (early removal from board reduces risk of decubitus ulcers)
2. *hypotension* (spinal shock): maintain SBP ≥ 90 mm Hg. Spinal cord injuries cause hypotension by a combination of factors (see Spinal shock (p. 1119)) which may further injure the spinal cord[3] or other organ systems
   a) pressors if necessary: dopamine is agent of choice (✖ avoid phenylephrine (Neosynephrine ®): non-inotropic and possible reflex increase in vagal tone → bradycardia)
   b) careful hydration (abnormal hemodynamics → propensity to pulmonary edema)
   c) atropine for bradycardia associated with hypotension
3. oxygenation (see above)
4. NG tube to suction: prevents vomiting and aspiration, and decompresses abdomen which can interfere with respirations if distended (paralytic ileus is common, and usually lasts several days)
5. indwelling (Foley) urinary catheter: for I's & O's and to prevent distension from urinary retention
6. DVT prophylaxis: see below
7. temperature regulation: vasomotor paralysis may produce poikilothermy (loss of temperature control), this should be treated as needed with cooling blankets
8. electrolytes: hypovolemia and hypotension cause increased plasma aldosterone which may lead to hypokalemia
9. more detailed neuro evaluation (p. 1127). Patients may be stratified using the ASIA impairment scale (▶ Table 68.13)
   a) focused history: key questions should center on:
      - mechanism of injury (hyperflexion, extension, axial loading…)
      - history suggestive of loss of consciousness
      - history of weakness in the arms or legs following the trauma
      - occurrence of numbness or tingling at any time following the injury
   b) palpation of the spine for point tenderness, a "step-off," or widened interspinous space
   c) motor level assessment
      - skeletal muscle exam (can localize dermatome)
      - rectal exam for voluntary anal sphincter contraction
   d) sensory level assessment

- sensation to pinprick (tests spinothalamic tract, can localize dermatome): be sure to test sensation in face also (spinal trigeminal tract can sometimes descend as low as ≈ C4)
- light (crude) touch: tests anterior cord (anterior spinothalamic tract)
- proprioception/joint position sense (tests posterior columns)

e) evaluation of reflexes
  - muscle stretch reflexes: usually absent initially in cord injury
  - abdominal cutaneous reflexes
  - cremasteric reflex
  - sacral: bulbocavernosus (p. 1130), anal-cutaneous reflex

f) examine for signs of autonomic dysfunction
  - altered patterns of perspiration (abdominal skin may have low coefficient of friction above lesion, and may seem rough below due to lack of perspiration)
  - bowel or bladder incontinence
  - persistent penile erection in males (priapism) or clitoris (clitorism) in females indicates autonomic dysfunction. May be a sign of complete SCI, or of spinal shock

10. radiographic evaluation: see below
11. medical management specific to spinal cord injury:
    a) methylprednisolone (see below)
    b) experimental/investigational drugs: none of these agents shown to have unequivocal benefit in man: naloxone, DMSO, Lazaroid®. Tirilazad mesylate (Freedox®) was less beneficial than methylprednisolone[4]

69.3.2 General information

Practice guideline: Assessment of SCI in the hospital

Clinical assessment

Level III[5]: the ASIA international standards for neurological and functional assessment of spinal cord injury (SCI) is recommended (p. 1129)

Functional outcome assessment

Level II[5]: the Functional Impairment Measure™ (FIM™) is recommended (see ▶ Table 98.7)

Level III[5]: the modified Barthel index is recommended (▶ Table 98.6)

Practice guideline: In-hospital critical care management of SCI

Level III[6]: monitor patients with acute SCI (especially those with severe cervical level injuries) in an ICU or similar monitored setting

Level III[6]: cardiac, hemodynamic & respiratory monitoring after acute SCI is recommended

Level III[7]: hypotension (SBP < 90 mm Hg) should be avoided or corrected ASAP

Level III[7]: maintain MAP at 85–90 mm Hg for the first 7 days after SCI to improve spinal cord perfusion

69.3.3 Methylprednisolone

Practice guideline: Methylprednisolone in SCI

Level I[8]

- Methylprednisolone (MP) for the treatment of acute SCI is not recommended.
- GM-1 ganglioside (Sygen) for the treatment of acute SCI is not recommended.

MP is not FDA approved for use in treating acute SCI. There is no Class I or II evidence of benefit supporting this use of MP. Class III data had been used to advocate its use, but the benefits were likely due to random chance and/or selection bias.[8] Conversely, there is Class I, II and III level evidence that high dose steroids are associated with harmful side effects and even death.[8] Use of high-dose MP among spine surgeons has shown a steady decline[9]; however, it was still used by as many as 56% of respondents to one survey.[9]

69.3.4 Hypothermia for spinal cord injury

The position statement of the joint sections of the AANS and the CNS is that there is not enough evidence to recommend for or against local or systemic hypothermia for acute SCI, and that it should be noted that systemic hypothermia is associated with medical complications in TBI.[10]

69.3.5 Deep-vein thrombosis in spinal cord injuries

General information

Also see Thromboembolism in neurosurgery (p. 176). Incidence of DVT may be as high as 100% when 125I-fibrinogen is used.[11] Overall mortality from DVT is 9% in SCI patients.

Practice guideline: DVT in patients with cervical SCI

Prophylaxis

Level I[12]:

- prophylactic treatment of venous thromboembolism (VTE) in patients with severe motor deficits due to SCI. Choices include:
    - LMW heparin, rotating beds, adjusted dose heparin, or some combination of these measures
    - or, low-dose heparin + pneumatic compression stockings or electrical stimulation

Level II[12]:

- early administration of VTE prophylaxis (within 72 hours)
- treat for 3 months
    - ✖ low-dose heparin should not be used alone
    - ✖ oral anticoagulation should not be used alone

Level III[12]:

- vena cava interruption filters should not be used for routine prophylaxis; they may be used for select patients who fail anticoagulation or are not candidates for anticoagulation

Diagnosis

Level III[12]:

- duplex Doppler ultrasound, impedance plethysmography, venography, and the clinical examination are recommended as diagnostic tests for DVT in patients with SCI

Prophylaxis

A study of 75 patients found titrating dose of SQ heparin q 12 hrs to a PTT of 1.5 times control resulted in lower incidence of thromboembolic events (DVT, PE) than “mini-dose” heparin (5000 U SQ q 12 hrs) (7% vs. 31%).[13] Heparin can cause thrombosis or thrombocytopenia, and chronic therapy may produce osteoporosis (see heparin (p. 172)).

69.4 Radiographic evaluation and initial C-spine immobilization

69.4.1 Clinical criteria to rule out cervical spine instability

There is almost no chance of a significant occult cervical spine injury[14,15] in a trauma patient who met all of the criteria in the Practice Guideline below. (**Note:** Although reports of bony or ligamentous abnormalities have be described as possibly occurring in these patients, there has been no report of a patient who had neurologic injury as a result of these abnormalities.)

Practice guideline: Radiographic evaluation in awake, asymptomatic trauma patients

Level I[16] & Level II[17,18]: radiographic studies are not indicated in patients who meet all of the following (these are basically the NEXUS Low-Risk Criteria[19]):

- no mental status changes (and no evidence of alcohol or drugs). Note: altered mental status can include GCS ≤ 14; disorientation to person, place, time, or events; inability to remember 3 objects at 5 minutes; delayed response to external stimuli. Evidence of alcohol or drugs includes information from the history, physical findings (slurred speech, ataxia, odor of alcohol on the breath) or positive blood or urine tests
- no neck pain or posterior midline tenderness (and no distracting pain)
- no focal neurologic deficit (on motor or sensory exam)
- do not have significant associated injuries that detract/distract from their evaluation

The Canadian C-Spine Rule (CCR) was found to be more sensitive & specific than the NEXUS driteria,[20] and is a valid alternative used by some, but was not endorsed by the EAST (Eastern Association for the Surgery of Spine Trauma) as of 2009.[17]

Cervical immobilization may be discontinued without cervical spine imaging in these patients.

69.4.2 Cervical immobilization

General information

Cervical collars should be removed as soon as it can be determined that it is safe to do so. The benefits from early collar removal include: reduction of skin breakdown,[21] fewer days of mechanical ventilation,[22] shorter ICU stays,[22] reduction of ICP.[23,24]

Guidelines

Guidelines for “clearing“ the cervical spine and removing the cervical collar are shown in **Practice guideline: Cervical immobilization in trauma patients** (p. 1142). A sample flow sheet is shown in

Practice guideline: Cervical immobilization in trauma patients

A cervical collar is not needed in trauma patients who meet these criteria

- Asymptomatic patients as in **Practice guideline: Radiographic evaluation in asymptomatic trauma patients** (p. 1142): patients who are alert, without neurologic deficit or distracting injury who have *no neck pain* or tenderness and full ROM of the cervical spine (Level II[17])
- Penetrating brain trauma: unless the trajectory suggests direct cervical spine injury (Level III[17])
- **Level II**[25] & **Level III**[17]: Patients who are awake *with* neck pain or tenderness and normal cervical CT scan after either (these tests are performed in the absence of an identifiable fracture or obviously unstable dislocation to rule out ligamentous or other soft-tissue injury that might be occult and unstable)
    - normal & adequate dynamic flexion-extension C-spine X-rays
    - or a normal cervical MRI is obtained. **Note:** AANS/CNS guidelines from 2002 recommended getting the MRI within 48 hours.[25] MRI is usually employed in this setting when the patient is unable to cooperate for flex-ext X-rays; see MRI findings and issues related to timing (p. 1145), etc.

In *obtunded* patients with normal cervical CT scan and gross movement of all 4 extremities

- ✖ flexion-extension C-spine X-rays should *not* be performed (Level II[17])
- options:
    - maintain cervical collar until a clinical exam can be performed[17]
    - remove the collar on the basis of the normal CT scan alone[17] (the incidence of ligamentous injury with negative CT is < 5%, and the incidence of clinically significant injury is unknown but is much < 1%[17])

- ○ obtain cervical MRI (AANS/CNS guidelines from 2002 recommended getting the MRI within 48 hours[25]) :
  - – Level III[17]: the risk and benefit of cervical MRI in addition to CT is unclear, and must be individualized
  - – Level II[17]: If the MRI is normal, the collar may be safely removed

69.4.3 Minimum radiographic evaluation

General information

There is controversy regarding what constitutes a minimum radiographic evaluation of the cervical spine in multiple trauma patient. No imaging modality is 100% accurate.

Asymptomatic patients—meeting criteria outlined in **Practice guideline: Radiographic evaluation in awake, asymptomatic trauma patients** (p. 1142)—may be considered to have a stable cervical spine and *no* radiographic studies of the cervical spine are indicated.[17,25] Factors associated with increased risk of failing to recognize spinal injuries include: decreased level of consciousness (due to injury or drugs/alcohol), multiple injuries, technically inadequate X-rays (p. 1221).[26]

Primary imaging recommendations

Practice guideline: Radiographic imaging in trauma patients who are obtunded or unevaluable

Includes unresponsive patients or unreliable exam (altered mental status, distracting pain or injuries)

- Level I[18]
  - ○ high-quality computed tomography (CT) imaging is the modality of choice
    ✖ if high-quality CT imaging is available, routine 3-view cervical spine X-rays are not recommended
  - ○ if high-quality CT imaging is not available, 3-view cervical spine X-rays (AP, lateral and open-mouth odontoid view) are recommended. Supplement with CT when available if needed to further define areas that are suspicious or poorly visualized on plain X-rays
- Level II[18]
  - ○ if high-quality CT imaging is normal but the index of suspicion is high, further management should fall to physicians trained in the diagnosis and treatment of spine injuries
- Level III[18]
  - ○ if high-quality CT imaging is normal, options include:
    - – continue cervical immobilization until asymptomatic
    - – obtain cervical MRI within 48 hours of injury and, if normal, D/C cervical immobilization*
    - – D/C cervical immobilization at the discretion of the treating physician
      ✖ the routine use of dynamic imaging (flexion-extension) is of marginal benefit and is not recommended in this situation

* limited and conflicting Class II & III medical evidence

CT scan, while extremely sensitive for bony injuries, is not adequate for assessing soft tissues (e.g., traumatic disc herniation, spinal cord contusion…) or ligamentous injuries (may require flexion-extension X-rays (see below) and/or MRI).

When CT scan is not appropriate/available as the initial radiographic exam

When CT cannot be done, the following guidelines are offered:

See **X-rays,** C-Spine (p. 222) for normal vs. abnormal findings. ▶ Table 69.2 lists some indicators that should alert the reviewer that there may be significant C-spine trauma (they do *not* indicate definite instability by themselves).

Table 69.2 Radiographic signs of C-spine trauma (modified[34])

Soft tissues
• retropharyngeal space > 7 mm, or retrotracheal space > 14 mm (adult) or 22 mm (peds), see ▶ Table 12.2 for details • displaced prevertebral fat stripe • tracheal deviation & laryngeal dislocation
Vertebral alignment
• loss of lordosis • acute kyphotic angulation • torticollis • widened interspinous space (flaring) • axial rotation of vertebra • discontinuity in contour lines (p. 222)
Abnormal joints
• ADI: > 3 mm (adult) or > 4 mm (peds) (see ▶ Table 12.1 for details) • narrowed or widened disc space • widening of apophyseal joints

1. cervical spine: must be cleared radiographically from the cranio-cervical junction down through and including the C7–1 junction (incidence of pathology at C7–1 junction may be as high as 9%[27]):
   a) lateral portable C-spine X-ray while in rigid collar: this study by itself will miss ≈ 15% of injuries[28]
   b) if all 7 cervical vertebrae *AND* the C7–1 junction are adequately visualized and are normal, and if the patient has no neck pain or tenderness and is neurologically intact (neurologically intact implies patient is alert, not drugged/intoxicated, & able to report pain reliably), then remove the cervical collar and complete the remainder of the cervical spine series (AP and open-mouth odontoid (OMO) view). Lateral, AP, and OMO views together detect essentially all unstable fractures in neurologically intact patients[29] (although the AP view rarely provides unique information[30]). In a severely injured patient, limitation to an AP and lateral view usually suffices for the *acute* (but not complete) evaluation[31]
   c) if the above studies are normal, but there is neck pain, tenderness or neurologic findings (there may be a spinal cord injury even with normal plain films), or if the patient is unable to reliably verbalize neck pain or cannot be examined for neurologic deficit, then further studies are indicated, which may include any of the following:
      - oblique views (some authors include oblique views in a “minimal” evaluation,[31] others do not[29]): demonstrates the neural foramina (may be blocked with a unilateral locked facet (p. 1186)), shows a different projection of the uncinate processes than the AP view, and helps assess the integrity of the articular masses and lamina (the lamina should align like shingles on a roof)[31]
      - flexion-extension views: see below
      - CT scan: helpful in identifying bony injuries, especially in areas difficult to visualize on plain radiographs. However, CT cannot exclude significant soft-tissue or ligamentous injury[32]
      - MRI: utility is limited to specific situation (p. 1146) and the accuracy has not been determined
      - polytomograms: becoming less available
      - pillar view: devised to demonstrate the cervical articular masses en face (reserved for cases suspected of having articular mass fracture)[33]: the head is rotated to one side (requires that the upper cervical spine injury has been excluded by previous radiographs), the X-ray tube is off centered 2 cm from midline in the opposite direction and the beam is angled 25° caudad, centered at the superior margin of the thyroid cartilage
   d) if subluxation is present at any level and is ≤ 3.5 mm and the patient is neurologically intact (neurologically intact implies patient is alert, not drugged/intoxicated, and able to report pain reliably), then obtain flexion-extension films (see below)
      - if no pathologic movement, may discontinue cervical collar
      - even if no instability is demonstrated, may need delayed films once pain and muscle spasms have resolved to reveal instability
   e) if *lower* C-spine (and/or cervical-thoracic junction) are not well visualized
      - repeat lateral C-spine X-ray with caudal traction on the arms (if not contraindicated based on other injuries, e.g., to shoulders)

    - if still not visualized, then obtain a "swimmer's" (Twining) view: the X-ray tube is positioned above the shoulder furthest from the film, and aimed towards the axilla closest to the film with the tube angled 10–15° toward the head while the arm is elevated above the head
    - if still not visualized: CT scan through non-visualized levels (CT is poor for evaluating alignment and for fractures in the horizontal plane, thin cuts with reconstructions ameliorates this shortcoming)
  f) see questions regarding stability of the subaxial spine (p. 1182)
  g) patients with C-spine fractures or dislocations should have daily C-spine X-rays during initial traction or immobilization
2. thoracic and lumbosacral LS-spine: AP and lateral X-rays for all trauma patients who:
   a) were thrown from a vehicle, or fell ≥ 6 feet to the ground
   b) complain of back pain
   c) are unconscious
   d) are unable to reliably describe back pain or have altered mental status preventing adequate exam (including inability to verbalize regarding back pain/tenderness)
   e) have an unknown mechanism of injury, or other injuries that cast suspicion of spine injury
3. reminder: when abnormalities of questionable vintage are identified, a bone scan may be helpful to distinguish an old injury from an acute one (less useful in the elderly; in an adult, a bone scan will become "hot" within 24–48 hrs of injury, and will remain hot for up to a year; in the elderly, the scan may not become hot for 2–3 weeks and can remain so for over a year)
4. if a bony abnormality is identified or if there is a level of neurologic deficit ascribable to a specific spinal level, either a CT or MRI scan through that area should be done if possible

Flexion-extension cervical spine X-rays

Purpose: to disclose occult ligamentous instability.

Rationale: It is possible to have a purely ligamentous injury (p. 1186) involving the posterior ligamentous complex and/or intervertebral disc without any bony fracture. Lateral flexion-extension views help detect these injuries, and also evaluate other injuries (e.g., compression fracture) for stability. For patients with limited flexion due to paraspinal muscle spasm (sometimes resulting from pain), a rigid collar should be prescribed, and 2–3 weeks later after the pain decreases[35] the flexion-extension films should be repeated.

Options: a cervical MRI done within 48–72 hours of the trauma (may be more sensitive with STIR sequences (p. 241) or equivalent) may identify ligamentous or other soft-tissue injury, especially in patients who cannot cooperate for flexion-extension X-rays.

✖ Contraindications

- the patient must be cooperative and free of mental impairment (i.e., no head injury, street or prescription drugs, alcohol…)
- there should not be any subluxation > 3.5 mm at any level on neutral lateral C-spine X-rays, which is a marker for possible instability (p. 1186)
- patient must be neurologically intact (if there is any degree of spinal cord injury, proceed instead first with imaging studies, e.g., MRI)
- F/E X-rays are no longer recommended in obtunded patients due to a low yield, poor cost-effectiveness, and they may be dangerous[17]

Technique

The patient should be sitting, and is instructed to flex the head slowly, and to stop if it becomes painful. Serial X-rays are taken at 5–10° increments (or followed under fluoro with spot films at the end of movement), and if normal, the patient may be encouraged to flex further. This is repeated until evidence of instability is seen, or the patient cannot flex further because of pain or limitation of motion. The process is then repeated for extension.

Findings

Normal flexion-extension views demonstrate slight anterior subluxation distributed over all cervical levels with preservation of the normal contour lines (▶ Fig. 12.1). Abnormal findings include: translational movement > 3.5 mm of one level on another, "flaring" of the spinous processes (see exaggerated widening (p. 224)).

Emergent MRI (or myelogram)

General information

Indications for *emergent* MRI in spinal cord injury (SCI) are listed below.

When an MRI cannot be performed, a *myelogram* is required (employing intrathecal contrast with CT to follow) ✖ Caution: cervical myelogram in patients with cervical spine injuries usually requires C1–2 puncture to achieve adequate dye concentration in the cervical region without dangerous extension of the neck or tilting of the patient as required when dye is injected via LP. Furthermore, pressure shifts from LP exacerbates deficit in 14% of cases with complete block.[36]

Indications

1. incomplete SCI (to check for R/O soft tissue compressing cord) with normal alignment: to check for soft tissue compressing cord
2. neurologic deterioration (worsening deficit or rising level) including after closed reduction
3. neurologic deficit not explained by radiographic findings, including:
   a) fracture level different from level of deficit
   b) no bony injury identified: further imaging is done to R/O soft tissue compression (disc herniation, hematoma…) that would require surgery
   c) always keep in mind the possibility of arterial dissection in this setting (p. 1576)

MRI (non-emergent)

General information

MRI may be used to identify potentially unstable occult ligamentous or soft tissue injury. Note: abnormal signal on MRI is not always associated with instability on flexion-extension X-rays.[37] It has been recommended that this MRI should be done within 48 hours[25] or 72 hours[38] of injury. MRI is not reliable for identifying osseous injury.

Indications for non-emergent MRI (modified):

See reference.[39]

1. inconclusive cervical spine radiography, including questionable fractures
2. significant midline paraspinal tenderness and patient unable to have flexion-extension X-rays
3. obtunded or comatose patients

T2WI and STIR (p. 241) are the most helpful sequences. Significant abnormal findings:

1. ventral signal abnormalities with prevertebral swelling
2. dorsal signal abnormalities. Abnormal signal limited to the interspinous is probably not as unstable as when it extends into the ligamentum flavum.[39] These patients were treated with rigid collars or Minerva jackets for 1–3 months, and one that was felt to be very unstable underwent fusion
3. disc disruption indicated by abnormal signal intensity within the disc, increased disc height, or frank disc protrusions

69.5 Traction/reduction of cervical spine injuries

69.5.1 General information

Purpose

To reduce fracture-dislocations, maintain normal alignment and/or immobilize the cervical spine to prevent further spinal cord injury. Reduction decompresses the spinal cord and roots, and may facilitate bone healing.

Practice guidelines

Practice guideline: Initial closed reduction in fracture-dislocation cervical SCI

Level III[40,41]

- early closed reduction of C-spine fracture-dislocation injuries with craniocervical traction to restore anatomic alignment in awake patients
- ✖ *not* recommended: closed reduction in patients with an additional rostral injury
- patients with C-spine fracture-dislocation who cannot be examined during attempted closed reduction, or before open posterior reduction, should undergo cervical MRI before attempted reduction (see note below). The presence of a significant herniated disc in this setting is a relative indication for anterior decompression (e.g., by an anterior cervical discectomy and fusion [ACDF]) before reduction
- cervical MRI is also recommended for patients who fail attempts at closed reduction (see note below)

Controversies

1. the rapidity with which reduction should be done[1]
2. whether MRI should be done prior to attempted closed reduction (prereduction MRI (p. 1147), will show disrupted or herniated discs in 33–50% of patients with facet subluxation. These findings do not seem to significantly influence outcome after closed-reduction in awake patients; ∴ the usefulness of prereduction MRI in this setting is uncertain)
   a) in intact patients, to R/O a condition that might cause worsening of neurologic condition with reduction (e.g., traumatic disc herniation)—must be balanced against risks of transferring patients to MRI
   b) in patients with neurologic deficit (complete or partial SCI)

✖ Contraindications

1. atlantooccipital dislocation (p. 1155): traction may worsen deficit. If immobilization with tongs/halo is desired, use no more than ≈ 4 lbs
2. types IIA or III hangman's fracture (p. 1165)
3. skull defect/fracture at anticipated pin site: may necessitate alternate pin site
4. use with caution in pediatric age group (do not use if age ≤ 3 yrs)
5. very elderly patients
6. demineralized skull: some elderly patients, osteogenesis imperfecta…
7. patients with an additional rostral injury
8. patients with movement disorders: constant motion may cause pin erosion through the skull

69.5.2 Application of tongs or halo ring

General information

Supplies: gloves, local anesthetic (typically 1% lidocaine with epinephrine), betadine ointment. Optional equipment: razor or hair clipper, scalpel.

Choice of device: a number of cranial "tongs" are available. Crutchfield tongs require predrilling holes in the skull. Gardner-Wells tongs are the most common tongs in use. If, after the acute stabilization, the later use of halo-vest immobilization is anticipated, a halo ring may be used for the initial cervical traction, and then converted to vest traction at the appropriate time (e.g., post-fusion).

Preparation: placed with patient supine on a gurney or bed. Option: shave hair around proposed pin sites (see below). Betadine skin prep, then infiltrate local anesthetic. Option: incise skin with scalpel (prevents pins from driving in surface contaminants).

Gardner-Wells tongs

Pin sites: the pins are placed in the temporal ridge (above the temporalis muscle), 2–3 fingerbreadths (3–4 cm) above pinna. Place directly above external acoustic meatus for *neutral* position traction; 2–3 cm posterior for *flexion* (e.g., for locked facets); 2–3 cm anterior for *extension*. One pin has a central spring-loaded force-indicator. Tighten pins until the indicator protrudes 1 mm beyond the flat surface. Retighten the pins daily until indicator protrudes 1 mm for 1 or 2 days only, then stop.

Halo ring

Supplies (in addition to above): optional paddle AKA "spoon" to support the head beyond the edge of the bed, traction adapter (called a "traction bail" from the circular handle on a baille, the old French word for bucket). Read all of this (including pointers) before starting

1. ring size: choose an appropriately sized ring that leaves a ≈ 1–2 cm gap between the scalp and the ring all the way around
2. ring position: generally placed at or just below the widest portion of the skull (the "equator"), but the front should be ≈ 1 cm above the orbital rim and the back should be ≈ 1 cm above the pinna.[42] To facilitate placement of the actual pins, the ring is usually temporarily stabilized with "pins" that have plastic discs where they contact the skull
3. pin sites: choose the threaded holes in the ring that place the pins as perpendicular to the skull as possible as follows
    a) anterior pins: above the *lateral* two–thirds of the orbit
    b) posterior pins: just behind the ears
    c) in pediatrics, additional pins may be placed to further distribute the load on the thinner skull
4. pin insertion: antibiotic ointment is usually places on the tips of the pins which are gradually brought close to the scalp which is then anesthetized with local anesthetic. Pins are then sequentially tightened, starting with any pin then going to the "kitty-corner" pin (diagonally opposite), then a third pin and finally its opposite. Most halos provide some type of torque wrench to permit approximately 8 in-lb of torque for most adults; 2–5 in-lb for peds
5. placement pointers
    a) the cervical collar is left in place until traction/immobilization is established
    b) try to place the halo as level from left to right as possible. Although compensation during vest placement can be made for a skewed ring, it looks bad
    c) prior to penetrating the forehead skin for anterior pins, have the patient close their eyes and hold them closed as the pins are advanced (this avoids "pinning the eyes open")
    d) ✖ avoid placing pins in the temporalis muscle or the temporal squamosa
    e) ✖ do not place pins above the medial third of the orbit to avoid the supraorbital and supratrochlear nerves, and to reduce the risk of penetrating the relatively thin anterior wall of the frontal sinus

Application of traction

For traction, transfer to a bed with ortho headboard with the tongs or halo ring/traction bail in place. Tie a rope to the tongs/traction bail and feed through a pulley at the head of bed. Slight flexion or extension is achieved by changing the height of the pulley relative to the patient's long axis.

X-rays: check lateral C-spine X-rays *immediately* after application of traction, at regular intervals, after every change in weights and every move from bed. Check alignment and rule out overdistraction at any level and atlantooccipital dislocation (p. 1153) (BDI should be ≤ 12 mm).

Weight: if there is no malalignment and traction is being used just to stabilize the injury and to compensate for ligamentous instability, use 5 lbs for the upper C-spine or 10 lbs for lower levels. See reducing locked facets (p. 1190) for information on that topic. The cervical collar may be removed once the patient is in traction with adequate reduction or stabilization.

Post-placement care

Pin tightening: pins are re-torqued in 24 hours. Some authors do one additional tightening the day after that. Avoid further tightenings thereafter which can penetrate the skull

Pin care: clean (e.g., half strength hydrogen peroxide), then apply povidone-iodine ointment. Frequency: in hospital: q shift. At home following discharge: twice daily. Alternatively, simple cleaning with soap and water twice daily is acceptable.

Application of halo vest

For vest placement (i.e., patients not remaining in traction) once the halo ring is placed (see above) it needs to be attached to the vest by posts. The mechanism varies between manufacturers. If possible, have the patient in a cotton T-shirt prior to placing the vest (this may require cutting the neck opening to accommodate the ring).

The vest should be snug, but too tight so as to restrict respirations. Shoulder straps should be contacting the shoulders (the vest will tend to ride up when the patient is sitting). Most vests come with a wrench that is taped to the vest for emergency removal e.g., for cardiopulmonary resuscitation.

Reduction of locked facets

See Practice guideline: Initial closed reduction in fracture-dislocation cervical SCI (p. 1147) for background information and Reduction of locked facets (p. 1190) for technique.

Complications

1. skull penetration by pins. May be due to:
   a) pins torqued too tightly
   b) pins placed over thin bone: temporal squamosa or over frontal sinus
   c) elderly patients, pediatric patients, or those with an osteoporotic skull
   d) invasion of bone with tumor: e.g., multiple myeloma
   e) fracture at pin site
2. reduction of cervical dislocations may be associated with neurologic deterioration which is usually due to retropulsed disc[43] and requires immediate investigation with MRI or myelogram/CT
3. overdistraction from excessive weight (especially with upper cervical spine injuries), may also endanger supporting tissues
4. caution with C1–3 injury, especially with posterior element fracture (traction may pull fragments in towards canal)
5. infection:
   a) osteomyelitis in pin sites: risk is reduced with good pin care
   b) subdural empyema (p. 350): rare[44,45]

69.6 Timing of surgery following spinal cord injury

69.6.1 Early surgery for spinal cord compression

Background information

The theoretical benefit of decompression is to restore blood flow to potentially salvageable spinal cord tissue. Improvement with early surgery has been demonstrated in animal studies. Attempts to confirm the benefit of surgical decompression in humans within 24 hours of injury has shown conflicting results. There has been considerable variability in practices related to the timing of surgery. Guidelines[46] addressing optimal timing of surgery for SCI have been based on weak clinical evidence.

Recent study findings

A meta-analysis[47] of 4 prospective, multicenter SCI databases[4,48,49,50] that were rated as high quality resulted in these findings:

- surgical decompression within 24 hrs of SCI was associated with improvement at 1 year in: mean motor scores, light touch & pinprick sensory scores, and ASIA Impairment Scale (▶ Table 68.13) grades
- post-op changes in total motor scores decreased as time to decompression from injury increased during the first 24-36 hours, and plateaued after 24-36 hours following SCI
- in cervical SCI, the motor score improvement associated with early decompression is greater in the UEs extending cranially starting at or just inferior to the injury level, than it is in the LEs

▶ **Caveats regarding these findings.** Other areas not addressed but which may be ripe for study[51]:

- functional and quality of life outcomes (the above studies only looked at neurologic outcomes, i.e., improved scores in grading scales)
- the 24 hour cutoff for “early surgery” is arbitrary, and it is unknown if “ultra-early” (< 8-12 hrs following SCI) would be even better

Remove collar

Fig. 69.1 Sample flowchart for "clearing" (i.e., removing) a rigid cervical collar after trauma.

* negative clinical findings (NEXUS criteria): no drugs/alcohol, TBI, confusion, distracting injury, neck pain or neurologic deficit

** CT 64 slice or higher Multi Detector CT (MDCT) is recommended. CT is not normal if fracture, dislocation or soft-tissue abnormality is demonstrated

† cervical MRI should be obtained within 48-72 hours of trauma because sensitivity decreases with time

§ treatment decision based on stability, neurologic/vascular involvement....

- these studies give no guidance as to what constitutes adequate decompression: e.g., is expansile duroplasty helpful?
- it is unknown if intrathecal pressure measurement would allow tailoring treatment measures (e.g., spinal cord perfusion pressure) to improve outcome
- if certain subgroups (e.g., central cord syndrome) don't benefit from early decompression
- it is unknown if complete SCI (i.e., ASIA A) benefits from early decompression
- is "after hours" early treatment (with its inherent limitations) more beneficial than waiting until the most proficient surgical team can be assembled for definitve treatment?

Cautious recommendations

Given the above limitations, it seems reasonable to state that:

∑: Surgery for SCI with ongoing compression

There is evidence that early decompression surgery (ideally within 24 hours, but possibly up to 36 hours, after injury) provides some benefit to neurologic function, and should be undertaken when feasible.

A Canadian study[52] found that this goal was attainable in < 50% of patients. Barriers to achieving this goal:

- patients who are medically unstable due to medical conditions or other injuries
- the time needed to obtain necessary diagnostic studies
- the time to transfer patients to centers that are capable of performing the needed surgery

69.6.2 Timing of surgery other than for decompression

Surgery for spinal *instability* as a result of fractures or ligamentous compromise when early surgery is not indicated should be performed within 72 hrs of injury whenever possible to permit earlier mobilization of the patient which is associated with lower rates of cardiac, respiratory and infectious complications.[53] As above, unavoidable delays may be encountered e.g., with medically unstable patients.

70 Occipitoatlantoaxial Injuries (Occiput to C2)

70.1 Atlantooccipital dislocation (AOD)

70.1.1 General information

See Occipitoatlantoaxial-complex anatomy (p. 67) for relevant anatomy.

Atlantooccipital dislocation (AOD), AKA craniocervical junction dislocation, AKA “internal decapitation” (in the lay press): disruption of the stability of the craniocervical junction (which results from *ligamentous* injuries). Probably underdiagnosed, may be present in ≈ 1% of patients with “cervical spine injuries”[1] (definition of cervical spine injuries not specified), found in 8–19% of fatal cervical spine injury autopsies.[2,3] More than twice as common in pediatrics as in adults, possibly owing to the flatter (i.e., less cupped) condyles in peds, the higher ratio of cranium-to-body weight, and increased ligamentous laxity. Most mortality results from anoxia due to respiratory arrest as a result of bulbar-cervical dissociation (BCD).

70.1.2 Clinical presentation

1. may be neurologically intact, therefore AOD must be ruled out in any major trauma
2. bulbar-cervical dissociation (p. 1132)
3. may have lower cranial nerve deficits (as well as VI palsies) ± cervical cord injury
4. cruciate paralysis (p. 1709)
5. worsening neurologic deficit with the application of cervical traction: check C-spine X-rays after applying traction, changing weights (see) (p. 1148)

70.1.3 Radiographic evaluation

Numerous methodologies have been devised to radiographically diagnose AOD. Most utilize *surrogate markers* for the end-point of interest: viz. instability of the occipital-cervical junction. None are completely reliable.[4] Measurements on CT scans are more accurate than plain radiographs (landmarks are easier to identify, no magnification or rotation error) – however, normal values differ from plain radiographs. Some methods are shown in ▶ Table 70.1. Recommended methods: BAI-BDI method and the AOI method (the AOI method is a level I recommendation[5] for diagnosing AOD in pediatrics).

Table 70.1 Radiographic evaluation of atlantooccipital dislocation (AOD)

Method	Comments	Normal values	
		Plain X-ray	CT
 **BAI-BDI method**[7a] Both BAI & BDI should be measured in adults.	**BAI**[8] (basion-axial interval) = distance from basion (inferior tip of the clivus) to rostral extension of posterior axial line (PAL) (the posterior cortical margin of the body of C2). AKA Harris line. Better for *anterior* or *posterior* AOD	Adults: -4 ≤ BAI ≤ 12 mm. Normal: BAI & BDI each ≤ 12 mm	May be used,[9] but was not reliably reproducible on CT[10]
		Peds: 0–12 mm (BAI should never be negative)	
	BDI (basion-dental interval) = distance from basion to the closest point on the tip of the dens. Better for *distracted* AOD	Adult: ≤ 12 mm (range: 2–15 mm) (mean: 7.5 ±þ4.3)	Adult: < 8.5 mm (range: 1.4–9 mm)[10]
		Peds: unreliable in age < 13 yrs because of variable age of ossification and fusion of the odontoid tip (os)	Peds[11b]: < 10.5 mm (95th percentile). With os[c]: < 9.5 mm. Without os[c]: < 11.5 mm

(continued)

Table 70.1 continued

Method	Comments	Normal values	
		Plain X-ray	CT
Atlantooccipital interval (AOI) AKA **CCI** (condyle-C1 interval) AKA **condylar gap.**[12] 	Distance between occipital condyle and superior articular surface of C1 measured on lateral X-ray or sagittal CT reconstructions thru O-C1 junction. Pang[13] averaged the interval between the condyle and C1 at 4 equidistant points on sagittal and 4 on coronal images (8 points total)	Adult[d]: ≤ 2 mm[12]	Adult: < 1.4 mm (95th percentile) (based on single measurement) [10]
		Peds: ≤ 5 mm (for all of 5 equally spaced measurements[14])	Peds: < 2.5 mm (single measure),[11] or < 4.0 mm (average of 8 measurements in 2 planes)[15]
Powers' ratio & **Dublin measure**  clivus Powers' ratio = BC/AO mandibular ramus B ≤ 13 mm A O Dublin C1 C ≤ 20 mm C2 POWERS' RATIO DUBLIN MEASURE	**Powers' ratio:** cannot be used with fractures of C1 or foramen magnum. Only for *anterior* AOD (see text). Requires identification of 4 reference points: B = basion, A = anterior arch of C1, C = posterior arch of C1, O = opisthion[e]	Adult: < 1 (range: 0.5–1.2) (95th percentile = 0.6–0.9) (see text for details)	Same as plain X-ray[10]
		Peds: < 0.9[f]	
	Dublin measure[16] 25% sensitive[17]	Mandible to anterior atlas: ≤ 13 mm. Posterior mandible to dens: ≤ 20 mm	
X-Line method 	AKA occipital-axial lines method.[17] Requires identification of 6 reference points and 2 lines (sensitivity 75%).[17] Uses a 6 ft target-film distance in a sitting patient[18] which is not always practical in the E/R[19] • C2O line: from the posteroinferior corner of axis body to the opisthion[e]. Should intersect tangentially with the highest point on the C1 spinolaminar line • BC2SL line: from the basion to a point midway on the C2 spinolaminar line. Should intersect tangentially with the posterosuperior dens		
MRI 	Abnormal MRI findings include: abnormal high signal on T2WI in the occipitoatlantal joints or in the posterior occipitoatlantal (O-C1) ligaments. Very sensitive (≈ 100%) but not specific for *unstable* AOD. The figure at left shows abnormal signal in the posterior O-C1 ligaments (arrow 1) and in the ligamentum flavum and soft tissues (arrow 2).		

[a] original study of lateral X-ray in a supine patient with a target-film distance of 40 in. (1 m). The sensitivity of the BAI-BDI method for AOD is good when all landmarks can be identified, but still may only be ≈ 75%[9]
[b] for this study, peds is defined up to the age of 10 years, by age ≈ 8–10 years the C-spine reaches adult proportions (not necessarily size)
[c] os = ossiculum terminale (p. 1175)
[d] the articular process of C1 is often obscured by the tip of the mastoid process on plain films
[e] the opisthion cannot be identified in ≈ 56% of lateral C-spine X-rays[8]
[f] could not be measured in many peds cases often due to lack of ossification (usually of posterior C1 arch)

▶ **Technical considerations for radiographic evaluation**

1. X-rays: verify that the film is a true lateral (e.g., check alignment of the two mandibular rami as well as of the posterior clinoids)
2. CT scan (bone windows)
    a) sensitivity, specificity, and positive/negative predictive values of most of these measures improve when sagittal CT views are used instead of plain radiographs[6] (relevant landmarks could be identified in > 99% of CTs, vs. 39–84% on X-ray)

b) indirect signs that may telegraph the presence of AOD include: blood in the basal cisterns and/or retroclival hematoma (p. 1102), on thin-cut axial CT there may be one or more slices showing no bone at all due to the gap between the occiput and C1

Practice guideline: Diagnosis of atlantooccipital dislocation

Level I[5]
- In pediatric patients, CT to assess the condyle-C1 interval (CCI) is recommended to diagnose AOD

Level III[5]
- In pediatric patients, CCI measured on CT has the highest sensitivity and specificity for AOD. The utility in adults has not been reported
- A lateral cervical spine X-ray is recommended to diagnose AOD. If it is desired to employ a radiologic method of measurement, the BAI-BDI method is recommended (see ▶ Table 70.1). Prevertebral soft tissue swelling in the upper cervical spine on an otherwise nondiagnostic X-ray should be followed with a cervical CT to rule out AOD

▶ **Powers' ratio.** Powers' ratio[1]: distance **BC** (basion to posterior arch of atlas) is divided by distance **AO** (opisthion to anterior arch of atlas), see ▶ Table 70.1. Interpretation is shown in ▶ Table 70.2.

✖ Cannot be used with any fracture involving the atlas or the foramen magnum, or with congenital anatomic abnormalities. Applies only to *anterior* AOD (i.e., not for posterior or distracted AOD).

Table 70.2 Powers' ratio

Ratio BC/AO	Interpretation	Comment
< 0.9	normal	1 standard deviation below the lowest case of AOD
≥ 0.9 and < 1	"gray zone" (indeterminate)	included 7% of normals and no cases of AOD
≥ 1	AOD	encompassed all AOD cases

▶ **Traynelis classification.**[20] Classifies the direction of the dislocation, as shown in ▶ Table 70.3.

Table 70.3 Traynelis directional classification of atlantooccipital dislocation* (AOD)[20]

Normal	Type I	Type II	Type III
			the inferior tip of the clivus should point directly to the tip of the dens (may be obscured on plain X-ray)	anterior dislocation of foramen magnum (FM) relative to the atlas	longitudinal dislocation (distraction)	posterior dislocation of FM

* Combinations (e.g., anterior-distracted AOD[19]) may also occur

70.1.4 Management

Initial management

If AOD is suspected, immediately immobilize the neck with halo orthosis or with sandbags.

✖ Cervical traction to reduce AOD is contraindicated because there is a 10% risk of neurologic deterioration.

Subsequent management

Controversial whether operative fusion vs. prolonged immobilization (4–12 months) with halo brace is required. However, posterior occipitocervical fusion is usually recommended (p. 1380).

Practice guideline: Treatment of atlantooccipital dislocation

Level III[5]

- internal fixation & arthrodesis (fusion) using one of a variety of methods
- ✖ CAUTION: cervical traction is not recommended in the management of AOD

Horn et al[9] suggest that patients be grouped and then managed as shown in ▶ Table 70.4.

In infants: reduce in the OR and fuse (usually with transarticular screws).

Table 70.4 Grading & management of AOD[9]

Grade	Definition	Management
I	no abnormal CT criteria[a] with only moderately abnormal MRI (high signal in posterior ligaments or occipitoatlantal joints)	external orthosis (halo or collar)
II	≥ 1 abnormal CT criteria[a] or grossly abnormal MRI findings in occipitoatlantal joints, tectorial membrane, or alar or cruciate ligaments	surgical stabilization

[a]CT criteria used: Power's ratio, BAI-BDI, X-line

70.1.5 Prognosis

The most important predictor of outcome is the severity of neurologic injuries at the time of presentation.[9] Among AOD patients who survived the initial injury, those with severe TBI and brainstem dysfunction or complete bulbar-cervical dissociation all had poor outcome.[9] Those with incomplete SCI or nonsevere TBI may improve.

70.2 Occipital condyle fractures

70.2.1 General information

Key concepts

- uncommon (0.4% of trauma patients)
- may present with lower cranial nerve deficits which may be delayed in onset (e.g., hypoglossal nerve palsy), mono-, para-, or quadriparesis or -plegia
- W/U: ✓ CT scan with reconstructions (rarely detected on plain X-rays)
- Treatment: usually with rigid collar. Indications for occipitocervical fusion or halo immobilization: craniocervical misalignment (occipital-C1 interval > 2.0 mm)

Occipital condyle fractures (OCF) were first described in 1817 by Bell.[21]

Rare. Incidence: 0.4% (in a series of 24,745 consecutive trauma patients surviving to the E/R[22]).

70.2.2 Diagnosis

Clinical suspicion of occipital condyle fracture (OCF) should be raised by the presence of ≥ 1 of the following[23]:

- blunt trauma with high energy
- craniocervical injuries
- altered consciousness

- occipital pain or tenderness
- impaired cervical movement
- lower cranial nerve palsies
- retropharyngeal soft-tissue swelling

Practice guideline: Diagnosis of occipital condyle fractures

Level II[24]
- CT to establish the diagnosis of occipital condyle fracture (OCF)

Level III[24]
- MRI to assess the integrity of the ligaments of the craniocervical complex

70.2.3 Classification

A widely used classification system is that of Anderson & Montesano[25] as shown in ▶ Table 70.5.

Maserati et al[22] classified patients simply on the basis of whether craniocervical misalignment was present or absent on CT with reconstructions (they defined craniocervical misalignment as an occipital condyle-C1 interval > 2.0 mm). They felt other classification systems were superfluous as they did not affect outcome in their retrospective review (see Treatment below).

Table 70.5 Anderson & Montesano classification of occipital condyle fractures

Type	Description	Treatment
I	comminuted from impact: may occur from axial loading	± external immobilization (collar or halo)
II	extension of linear basilar skull fracture[26]	± external immobilization (collar or halo)
III	*avulsion* of condyle fragment (traction injury): may occur during rotation, lateral bending, or a combination of mechanisms. Considered unstable by many	external immobilization (collar or halo) X 6–8 weeks

70.2.4 Treatment

Controversial. Lower cranial nerve deficits often develop in untreated cases of OCF, and may resolve or improve with external immobilization. Anderson & Montesano Types I & II have been treated with or without external immobilization (cervical collar or, occasionally, halo) without obvious difference (▶ Table 70.5). External immobilization × 6–8 weeks is suggested for Type III fractures because of the higher risk of delayed deficits.

Treatment guidelines are also shown.

Practice guideline: Treatment of occipital condyle fractures

Level III[24]:
- For OCF with associated atlantooccipital ligamentous injury or evidence of instability: halo vest immobilization or occipitocervical stabilization (fusion).
- For bilateral OCFs, consider halo vest instead of a collar to provide increased immobilization.
- External cervical immobilization for all other OCFs.

70.2.5 Outcome

In a retrospective review of 100 patients with OCF,[22] 3 patients underwent occipitocervical fusion (p. 1773) for craniocervical misalignment (2) or unrelated C1–2 fracture (1). The remainder (without craniocervical misalignment) were treated with a rigid collar and delayed clinical & radiographic follow-up. None of their unoperated patients had neurologic deficit, and none developed delayed instability, malalignment, or neurologic deficit (regardless of their classification on the other systems in use).

70.3 Atlantoaxial (C1-2) subluxation/dislocation

70.3.1 General information

Lower morbidity and mortality than atlantooccipital dislocation.[27] See Occipitoatlantoaxial-complex anatomy (p. 67) for relevant anatomy.

Types of atlantoaxial subluxation:

1. anterior subluxation (p. 1160): more ominous
2. rotatory: (see below) usually seen in children after a fall or minor trauma
3. anterior subluxation (p. 1160): more ominous. The most common type of C1-2 dislocation
4. posterior: rare. Usually from erosion of odontoid. Unstable. Requires fusion
5. distraction (p. 1162): increased separation between C1 & C2 (BDI (p. 1153) increases in the absence of AOD)

70.3.2 Atlantoaxial rotatory subluxation

General information

70

Key concepts

- typically seen in children
- associations: trauma, RA, respiratory tract infections in peds (Grisel syndrome)
- often presents with cock-robin head position (tilt, rotation, slight flexion)
- classification: Fielding & Hawkins (▶ Table 70.6)
- Tx: early traction is often successful. Treat infection in Grisel syndrome. Subluxation unreducible in traction may need transoral release then posterior fusion

Rotational deformity at the atlanto-axial junction is usually of short duration and easily corrected. Rarely, the atlantoaxial joint locks in rotation (AKA atlantoaxial rotatory *fixation*[28]). Usually seen in children. May occur spontaneously (with rheumatoid arthritis[29] or with congenital dens anomalies), following major or minor trauma (including neck manipulation or even with neck rotation while yawning[28]), or with an infection of the head or neck including upper respiratory tract (known as Grisel syndrome[30]: inflammation may cause mechanical and chemical injury to the facet capsules and/or transverse atlantal ligament (TAL)).

The vertebral arteries (VA) may be compromised in excessive rotation, especially if it is combined with anterior displacement.

Mechanism of subluxation

The dislocation may be at the occipito-atlantal and/or the atlanto-axial articulations.[31] The mechanism of the irreducibility is poorly understood. With an intact TAL, rotation occurs without anterior displacement. If the TAL is incompetent as a result of trauma or infection, there may also be anterior displacement with more potential for neurologic injury. Posterior displacement occurs only rarely due to incompetence of the odontoid.[28]

Classification

The Fielding and Hawkins classification[28] is shown in ▶ Table 70.6.

Clinical findings

Patients are usually young. Neurologic deficit is rare. Findings may include: neck pain, headache, torticollis—characteristic "cock robin" head position with ≈ 20° lateral tilt to one side, 20° rotation to the other, and slight (≈ 10°) flexion, see DDx (p. 1677), reduced range of motion, and facial flattening.[28] Although the patient cannot reduce the dislocation, they can increase it with head rotation towards the subluxed joint with potential injury to the high cervical cord.

Table 70.6 Fielding & Hawkins classification of rotatory atlantoaxial subluxation[28]

Type	Description		AD[a] (mm)	Comment
	TAL[a]	**Facet injury**		
Type I 	intact	bilateral	≤ 3	the most common. Dens acts as pivot
Type II 	injured	unilateral	3.1–5	intact facet joint acts as pivot
Type III 	injured	bilateral	> 5	rare. Very unstable. Risk of neurologic injury
Type IV 	incompetence of the odontoid (e.g., fracture or erosion) with *posterior* displacement of C1			rare. Very unstable. High risk of neurologic injury

[a] AD = anterior displacement of C1 on C2, TAL = transverse atlantal ligament

Brainstem and cerebellar infarction and even death may occur with compromise of circulation through the VAs.[32]

Radiographic evaluation

X-rays : findings (may be confusing) include:

- pathognomonic finding on AP C-spine X-ray in severe cases: frontal projection of C2 with simultaneous oblique projection of C1.[33 (p 124)] In less severe cases, the C1 lateral mass that is anterior appears larger and closer to the midline than the other
- asymmetry of the atlantoaxial joint that is not correctable with head rotation, which may be demonstrated by persistence of asymmetry on open mouth odontoid views with the head in neutral position and then rotated 10–15° to each side
- the spinous process of the axis is tilted in one direction and rotated to the other (may occur in torticollis of any etiology)

CT scan: demonstrates rotation of the atlas.[31]

MRI: may assess the competence of the transverse ligament.

Treatment

Grisel syndrome

Appropriate antibiotics for causative pathogen with traction (see below) and then immobilization for the subluxation as follows[30]: Fielding (▶ Table 70.6) Type I: soft collar, Type II: rigid collar or SOMI, Type III or IV: halo. After 6–8 weeks of immobilization, check stability with flexion-extension X-rays. Surgical fusion for residual instability.

Traction

If treated within the first few months,[34] the subluxation can usually be reduced with gentle traction (in children start with 7–8 lbs and gradually increase up to 15 lbs over several days, in adults start with 15 lbs and gradually increase up to 20). If the subluxation is present > 1 month, traction is less successful. Active left-right neck rotation is encouraged in traction.

If reducible, immobilization in traction or halo is maintained × 3 months[28] (range: 6–12 weeks).

Surgical fusion

Subluxation that cannot be reduced or that recurs following immobilization should be treated by surgical arthrodesis after 2–3 weeks of traction to obtain maximal reduction. The usual procedure is C1 to C2 fusion (p. 1778) unless other fractures or conditions are present.[28] Fusion may be performed even if the rotation between C1 & C2 is not completely reduced. For irreducible fixation, a staged procedure can be done with anterior transoral release of the atlantoaxial complex (the exposure is taken laterally to expose the atlantoaxial joints, which must be done carefully to avoid injury to the VAs, soft tissue is carefully removed from the joints and the atlantodental interval, no attempt at reduction was made at the time of this 1st stage), followed by gradual skull traction and then a second stage posterior C1–2 fusion.[34]

70.3.3 Anterior atlantoaxial subluxation (AAS)

General information

One third of patients with AAS have neurologic deficit or die.[27] For relevant anatomy, see Occipitoatlantoaxial-complex anatomy (p. 67).

Subluxation may be due to:

1. disruption (rupture) of the transverse atlantal ligament (TAL): the atlantodental interval (ADI) (see below) will be increased
    a) attachment points of the TAL may be weakened in rheumatoid arthritis (p. 1778)
    b) trauma: may cause anatomic or functional ligament disruption (see below)
2. incompetence of the odontoid process: ADI will be normal
    a) odontoid fracture
    b) congenital hypoplasia, e.g., Morquio syndrome (p. 1309)

Presentation

Neck pain is common. There are no specific patterns to the pain that are characteristic.

"V" shaped pre-dens space

Widening of the upper space between the anterior arch of C1 and the odontoid seen on lateral C-spine flexion X-ray.[35] It is not known if this increased mobility represents elongation or laxity of the transverse ligament and/or the posterior ligamentous complex. This may also be a normal finding in flexion in peds.

True subluxation will result in malalignment between C1 and C2. The key differentiating feature is whether the ADI is increased or normal, as indicated above.

Evaluation and classification

Diagnostic modalities

Both CT & MRI are recommended to evaluate fractures, TAL & its bony attachments.

Injury of the transverse atlantal ligament (TAL)

Assessing the integrity of the TAL

1. TAL disruption may be inferred *indirectly*. from
   a) rule of Spence (p. 223): if the total overhang (lateral mass displacement (LMD)) of both C1 lateral masses on C2 is ≥ 7 mm (NB: this rule is inaccurate and should not be used as the sole determinant)
   b) atlantodental interval (ADI) (p. 223): > 3 mm in adults, > 4 mm in peds
2. direct assessment: there is concern that indirect assessment above has low sensitivity (the rule of Spence missed 60% of TAL injuries detected on MRI[36]). MRI may be able to directly assess TAL integrity by imaging it. Possible findings: loss of continuity of the TAL, high signal within the TAL on gradient-echo MRI, blood separating the TAL from its insertion site on the medial tubercle. For subtypes of TAL injury, see below
3. CT may demonstrate bony injury in the regions of TAL insertion on C1 tubercles

70

Dickman classification of transverse atlantal ligament (TAL) disruption

See reference.[36]

Obtain high-resolution axial MRI using surface coils with fast-spin echo, gradient-echo T1WI & T2WI sequences.[36,37] Not recommended for patients < 14 years of age due to immaturity of the spine. Clinical use of this classification has not been validated.[38]

► **Dickman Type I.** Anatomic disruption. Tear of TAL itself without osseous component. Rare (the odontoid usually fractures before the TAL tears). Unlikely to heal. Requires surgical stabilization. Subtypes:

1. Type IA: midsubstance TAL disruption. Possible findings:
   1. loss of continuity of the TAL
   2. high signal within the TAL on gradient-echo MRI
2. Type IB: osteoperiosteal TAL disruption. Possible finding: blood separates the TAL from its insertion site on the medial tubercle

► **Dickman Type II.** Physiologic disruption. Detachment of the C1 tubercle (to which TAL is attached) (► Fig. 1.14) from the C1 lateral mass. May occur in comminuted C1 lateral mass fractures. 74% chance of healing with immobilization (halo recommended[36])

Treatment

- for TAL disruption: one approach is as follows[36,39]
  - fuse all Dickman Type I TAL injuries at diagnosis
  - fuse Dickman Type II TAL injuries that are still unstable after 3–4 months of immobilization
- fusion is also recommended with irreducible subluxations.
- if C1 is intact, a C1–2 fusion is usually adequate. If C1 is fractured, occipital cervical fusion may be needed
- for situations involving isolated C1 fractures, see below
- for odontoid fractures with intact TAL, see guideline (p. 1173)

70.3.4 Atlantoaxial distraction injuries

Rare. A purely distractive injury without disruption of the TAL or fracture of the odontoid process would require injury to the tectorial membrane, ascending and descending bands of the cruciate ligament, alar ligaments, and capsular and accessory C1-2 ligaments (see ▶ Fig. 1.12, ▶ Fig. 1.13, ▶ Fig. 1.14).[40]

70.4 Atlas (C1) fractures

70.4.1 General information

Key concepts

- the primary classification systems are the Jefferson and the Landell
- no Level I or II data to determine optimal treatment
- TAL (transverse atlantal ligament) integrity is a critical for stability
- Tx: all but the most unstable injuries (viz.: anterior + posterior ring fractures with TAL disruption) can be managed with a trial period in a rigid collar for 3-4 months, with surgery reserved for treatment failures

Sir Geoffrey Jefferson described a four-point (burst) fracture of the C1 ring in 1920.[41] The term now includes any burst fracture of C1[42] (3 or 2-point fractures are more common[43] the latter usually through the C1 arches (thinnest part)). Usually from *axial* loading (a “blow-out” fracture).[44]

Acute C1 fractures account for 3–13% of cervical spine fractures.[45] 56% of 57 patients had isolated C1 fractures; 44% had combination C1–2 fractures; 9% had additional non-contiguous C-spine fractures. 21% had associated head injuries.[45]

In pediatrics, it is critical to differentiate a C1 fracture from the normal synchondroses (p. 224) (a fracture may also occur through unfused synchondroses) and from pseudospread of the atlas (p. 1123).

70.4.2 Clinical

Neurologic deficit is rare with isolated C1 fractures due to the large canal diameter at this level, plus the tendency for fragments to be forced outwards away from spinal cord. Possible clinical findings[39]:

1. neck pain is common and the patient will often guard against movement
2. prevertebral swelling may impinge on the esophagus and cause swallowing difficulties
3. pain in the distribution of the greater occipital nerve may occur from C2 root involvement (p. 541)
4. associated vertebral artery dissection (p. 1579) may produce symptoms of posterior circulation ischemia (diplopia, altered level of consciousness, lateral medullary syndrome…)
5. lower cranial nerve (IX-XII) palsies have also been reported

70.4.3 Evaluation

Modalities

Thin cut high-resolution CT is the diagnostic test of choice. It is critical to evaluate from C1 through C3 to delineate details of the C1 fracture and to assess for associated C2 injury.

MRI may be able to directly evaluate the integrity of the TAL,[36] but this may be difficult to assess in a number of cases (p. 1161).

Stability

To reiterate: stability of the occipitoatlantoaxial complex is primarily due to ligaments, with little contribution from bony articulations. See Occipitoatlantoaxial-complex anatomy (p. 67).

★ Integrity of the transverse (atlantal) ligament (TAL) is the most important determinant of stability in C1 fractures (see Assessing the integrity of the TAL (p. 1161)).

70.4.4 Classification of C1 fractures

Representative examples of the Jefferson classification[41] are shown in ▶ Table 70.7 (Jefferson type III is the classic 4-point Jefferson fracture). The practice guidelines are based on the Landells classification[46] which is also illustrated in ▶ Table 70.7).

Table 70.7 Classification and management of isolated C1 (atlas) fractures

Landells class[46]	**Illustration & Jefferson Classification[41]**	**Treatment recommendations[a] [38]**
Type I posterior arch alone or anterior arch alone (single arch) 31–45% of C1 fractures		rigid immobilization[b] X 8–12 weeks[c]
Type II anterior AND posterior arch ("burst fracture") 37–51%		**TAL intact[d]** (i.e., stable) • rigid immobilization[b] X 10–12 weeks[c] **TAL disrupted[d]** (i.e., unstable) • halo[e] X 12 weeks • or surgical stabilization & fusion
Type III lateral mass fractures (comminuted) 13–37%		rigid immobilization[b] X 8–12 weeks[c]

[a] treatment recommendations are based on the text accompanying the 2013 practice guidelines.[42] To also consider subtypes of injuries to the TAL, see schema (p. 1164)

[b] there is insufficient evidence to recommend any of the following cervical immobilization devices over the other: rigid collar, SOMI (sternal-occipital-mandibular immobilizer), halo-vest[42]

[c] at the end of nonsurgical treatment, surgical fusion is recommended for late instability e.g., on flexion/extension C-spine X-rays[39,42]

[d] suggested criteria for TAL disruption include: LMD overhang ≥ 7 mm (rule of Spence (p. 1161), NB: this rule is inaccurate and should not be used as the sole determinant), atlantodental interval (ADI) (p. 223) > 5 mm in adults (this is the ADI used for the guidelines[42]; other authors use different cutoffs for the ADI, e.g., 3 mm[36]), or evidence of disruption or avulsion of the TAL on MRI

[e] although evidence is lacking, some prefer halo-vest for unstable C1 fractures[42]

Abbreviations: TAL = transverse atlantal ligament; LMD = lateral mass displacement.

70.4.5 Treatment decisions

Treatment guidelines

There is no Level I or II evidence for optimal treatment. Treatment recommendations depend primarily on the status of the TAL. Practice guidelines[42] are shown below, with associated treatment specifics, such as length of treatment, appearing in ► Table 70.7. For combination C1 & C2 injuries, see section 70.6.

Practice guideline: Treatment of isolated atlas fractures

Level III[42]

- treatment is based on the fracture type and integrity of the transverse atlantal ligament (TAL)
- if the TAL is intact[a]: cervical immobilization alone[b, c] (for Landells types I & III, nondisplaced fractures have been effectively treated with external immobilization)
- if the TAL is disrupted[a]: either
  a) cervical immobilization alone[b, c, d]
  b) or surgical fixation and fusion

[a]suggested criteria for TAL disruption include: LMD (overhang) ≥ 7 mm (rule of Spence (p. 1161) - NB: this rule is inaccurate and should not be used as the sole determinant), atlantodental interval (ADI) (p. 223) > 5 mm in adults (this is the ADI used for the guidelines[42]; other authors use different cutoffs, e.g., 3 mm for the ADI[36]), or evidence of disruption or avulsion of the TAL on MRI.

[b]there is insufficient evidence to recommend any of the following cervical immobilization devices over the other: rigid collar, SOMI (sternal-occipital-mandibular immobilizer), halo-vest[42]

[c]at the end of nonsurgical treatment, surgical fusion is recommended for late instability e.g., on flexion/extension C-spine X-rays[39,42]

[d]although evidence is lacking, some prefer halo-vest when there is TAL disruption (unstable fractures)[42]

Abbreviations: LMD = lateral mass displacement; TAL = transverse atlantal ligament.

Barrow Neurologic Institute (BNI) management guidelines for isolated C1 fractures

Based on the importance of TAL integrity and the assertion that pure ligamentous injuries of the TAL have a lower chance of healing than functional injuries resulting from fracture of the bone supporting the tubercle where the TAL is attached,[36] the following managment protocol was developed[39] (using the Dickman classification (p. 1161) and the lateral mass displacement (LMD)) (p. 223). It has been pointed out that the methodology of this protocol is not sufficient to classify the level above Class III medical evidence[42]; however, that is not very different from the level of recommendations in the current guidelines.

► **BNI treatment protocol for isolated C1 (atlas) fractures.** Evaluation: unless contraindicated, all patient's are evaluated with cervical MRI to assess the integrity of the TAL (p. 1161) and thin-cut cervical CT to assess the fracture. Lateral mass displacement (LMD) (p. 223) is measured in all cases.

1. Dickman Type I TAL disruption (pure ligamentous injury): surgical fusion
2. the following may be treated with immobilization for 3 months after which flexion/extension C-spine X-rays are obtained, and surgical fusion is performed if unstable
   a) TAL intact on MRI and LMD < 7 mm: cervical collar X 3 months
   b) Dickman Type II TAL disruption (bony avulsion) or LMD ≥ 7 mm: halo X 3 months

70.4.6 Surgical options

Fusion options when surgery is indicated:

1. unilateral ring or anterior C1 arch fractures: C1–2 fusion
2. multiple ring fractures or posterior C1 arch fractures: occipital-cervical fusion

Surgical options that do not involve arthrodesis:

1. posterior C1 screw placement
2. anterior transoral screw/plate placement

70.4.7 Outcome

In many series,[45,47] treatment without surgery results in satisfactory radiographic outcome when the TAL is not disrupted.

Even with a satisfactory X-ray result, 20–40% of patients have neck pain after rigid immobilization.[39]

Late complications may include basilar invagination as a result of telescoping of the odontoid through the splayed ring of C1 into the foramen magnum.

70.5 Axis (C2) fractures

70.5.1 General information

Acute fractures of the axis represent ≈ 20% of cervical spine fractures. Neurological injury is uncommon (occurs in < 10% of cases). Most injuries may be treated by rigid immobilization.

Steele's rule of thirds: each of the following occupies one–third of the area of the canal at the level of the atlas (C1): dens, space, spinal cord (▶ Fig. 110.2).[48]

70.5.2 Types of C2 fractures

1. odontoid fractures (p. 1171): type II odontoid fracture is the most common injury of the axis
2. hangman's fracture: see below
3. miscellaneous C2 fractures (p. 1177)

70.5.3 Hangman's fracture

General information

70

Key concepts

- bilateral fracture through the pars interarticularis of C2 with traumatic subluxation of C2 on C3, most often due to hyperextension + axial loading
- most are stable with no neurologic deficit
- classification: Levine system (▶ Table 70.8). Critical dividing line: disruption of C2–3 disc (Types II and higher) which may render the fracture unstable
- W/U: ✓ cervical CT with sagittal & coronal recons for all. ✓ Cervical MRI to assess C2–3 disc disruption (Levine II). ✓ CTA for dissection if fx passes thru foramen transversarium (consider for all C2 fractures—see ▶ Table 61.8)
- most do well with non-halo immobilization x 8–14 weeks. Exceptions: severe/unstable fractures (p. 1166) or those that do not remain aligned in brace

AKA traumatic spondylolisthesis of the axis (a term first used in 1964[49]).

Description: bilateral fracture through the pars interarticularis (isthmus) of the pedicle of C2 (▶ Fig. 70.1; the configuration of C2 is unique, and the distinction between the pars and the pedicle is ambiguous). There is often anterior subluxation of C2 on C3.

The term "hangman's fracture" (HF) was coined by Schneider et al,[50] although the mechanism of most modern HFs (hyperextension and *axial loading*, from MVAs or diving accidents) differs from that sustained in judicial hangings (where submental placement of the knot results in hyperextension and distraction[51]). Some cases may be due to forced flexion or compression of the neck while in extension.

Pediatrics: rare in children < 8 years old where the forces tend to fracture the incompletely fused odontoid, see epiphyseal fracture (p. 224). In pediatrics, consider pseudosubluxation in the differential diagnosis (p. 1123).

Usually *stable*. Deficit is rare. Nonunion is rare. 90% heal with immobilization only. Operative fusion is rarely needed. Fractures of C2 that do not go through the isthmus (p. 1177) are not true hangman's fractures and may require different management.

Classification

Levine/Effendi classification

The system of Effendi et al[52] as modified by Levine[53] and others (▶ Table 70.8) is widely used in grading adult HF (not applicable to peds). Angulation is measured as the angle between the inferior endplates of C2 and C3. Anterior subluxation of C2 on C3 > 3 mm (Type II) is a surrogate marker for C2–3 disc disruption, which can be evaluated more directly with cervical MRI.

Grading system of Frances et al

The grading system[56] is shown in ▶ Table 70.9.

The methodology of measurements is depicted in ▶ Fig. 70.2.

Levine/Francis correlation

In a series of 340 axis fractures,[57] the most common fracture type was Type I in the Levine system (72%) and Grade I in the Francis system (65%); there was a close correlation as follows:

Levine Type I ≈ Francis Grade I
Levine Type III ≈ Francis Grade IV

Other fracture types

Not all fractures fit into one or both of these classification systems.[58] Example: coronally oriented fracture extending through the posterior C2 vertebral body.

Presentation

Most (≈ 95%) are neurologically intact, those few with deficits are usually minor (paresthesias, monoparesis…) and many recover within one month.[56] Almost all conscious patients will have cervical pain usually in the upper posterior cervical region, and occipital neuralgia is not uncommon.[59] There is a high incidence of associated head injury and there will be other associated C-spine injuries —e.g., C1 fracture (see above) or clay shoveler’s fracture (p. 1183)—in ≈ one third, with most occurring in the upper 3 cervical levels. There are usually external signs of injury to the face and head associated with the hyperextending and axial force.

Table 70.8 Levine classification of hangman's fractures (modified Effendi system)[a]

Type	Description	Radiographic findings	Mechanism	Comment
I	vertical pars fx just posterior to the VB	≤ 3 mm subluxation of C2 on C3 & *no* angulation	axial loading & extension	stable on flexion/extension X-rays. Neurologic deficit rare
I A	fx lines on each side are not parallel. Fx may pass thru *foramen transversarium* on one side	fx line may not be visible on X-ray. *Anterior* C2 VB may be subluxed 2–3 mm anteriorly on C3 & the C2 VB may appear elongated	may be hyperextension + lateral bending	"atypical hangman's fracture."[54] Spinal canal may be narrowed. 33% incidence of paralysis
II	vertical fx thru pars. *Disruption of C2–3 disc* & posterior longitudinal ligament	subluxation of C2 on C3 > 3 mm and/or angulation[b]. Slight anterior compression of C3 possible	axial loading & extension with rebound flexion	may lead to early instability. Neurologic deficit rare. Usually reduces with traction
IIA	oblique fx (usually anterior-inferior to posterior superior)  little subluxation (usually ≤ 3 mm) but more angulation (can be > 15°)		flexion distraction (posterior arch fails in tension)	rare (< 10%). Unstable. ✖ Traction → increased angulation & widening of disc space ∴ *do not use* traction
III	Type II + bilateral C2–3 facet capsule disruption. C2 posterior arch is free floating. Anterior longitudinal ligament may be disrupted or stripped off C3	facets of C2/C3 may be subluxed or locked	unclear, may be flexion (capsule disruption) followed by compression (isthmus fracture)	rare. Neurologic deficit may occur & may be fatal. Facet dislocation usually cannot be reduced by closed reduction. ✖ Traction may be dangerous (see text)

[a] Effendi et al,[52] Levine and Edwards,[53] Sonntag and Dickman,[27] and Levine[55]
[b] amount of angulation was not specified in original article, but > 10° has been suggested by some

Table 70.9 Francis grading[a] system for hangman's fracture

Grade	Angulation θ	Displacement
I	< 11°	d < 3.5 mm
II	> 11°	
III	< 11°	d > 3.5 mm and d/b < 0.5
IV	> 11°	
V		d/b > 0.5 (disc disruption)

[a] see ▶ Fig. 70.2 for illustration of θ, d & b

Evaluation

Cervical CT: with sagittal & coronal reconstructions should be done to fully assess the fracture.

CTA: should be done to evaluate the vertebral arteries if fracture extends through foramen transversarium (especially Levine Type IA) and in patients with symptoms suggestive of stroke. Some recommend CTA for all C2 fractures—see ▶ Table 61.8). Angiography or MRA may be done as an alternative to CTA.

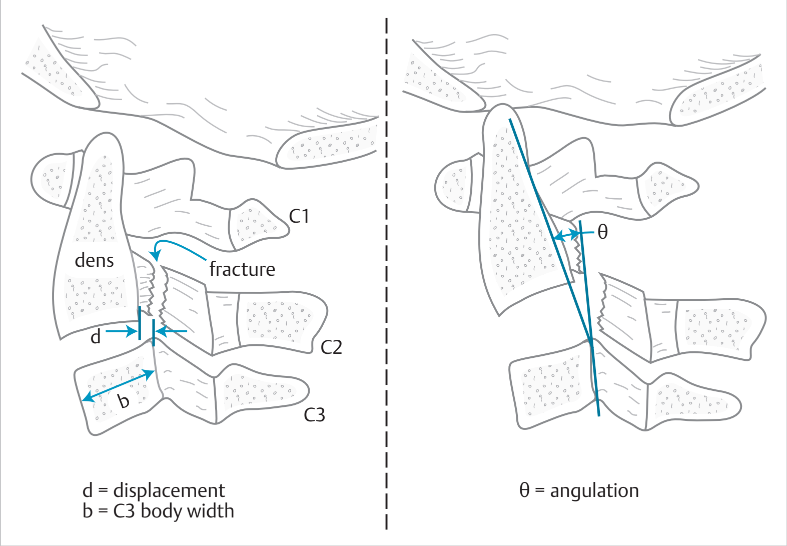

Fig. 70.2 Parameters used in the Francis grading system for hangman's fractures.

★ **MRI**: cervical MRI should be done to look for C2–3 disc disruption (a marker for instability (▶ Fig. 70.3) (Levine grade II) which usually requires surgical stabilization). Findings include abnormal increased signal intensity on MRI (best seen on sagittal FLAIR images or T2WI) or significant distraction across the disc space.

X-rays: lateral C-spine X-rays show the fracture in 95% of cases. Also demonstrates C2 angulation and/or subluxation. Most fractures pass through the pars or the transverse foramen,[56] 7% go through the body of C2 (p. 1177). Instability can usually be identified as marked anterior displacement of C2 on C3 (guideline[56]: unstable if displacement exceeds 50% of the AP diameter of C3 vertebral body), excessive angulation of C2 on C3, or by excessive motion on flexion-extension films.

Patients suspected of having Levine Type I fractures and are neurologically intact should have physician-supervised flexion-extension X-rays to rule out a reduced type II fracture.

Treatment

General information

Nonsurgical management produces adequate reduction in 97–100% and results in a fusion rate of 93–100%[27,60,61] if the external immobilization is adequately maintained for 8–14 weeks[62] (average time for healing is ≈ 11.5 weeks[56]). Specific treatment depends on the reliability of the patient and the degree of stability as described below. Most cases do well with non-halo immobilization.[61] Practice guidelines are shown here, and details follow.

Practice guideline: Management of isolated hangman's fracture

Level III[38,63]

- hangman's fractures may initially be managed with external immobilization in most cases (halo or collar)
- surgical stabilization should be considered in cases of:
  - a) severe angulation of C2 on C3 (Levine II, Francis II & IV)
  - b) disruption of the C2–3 disc space (Levine II, Francis V)
  - c) or inability to establish or maintain alignment with external immobilization

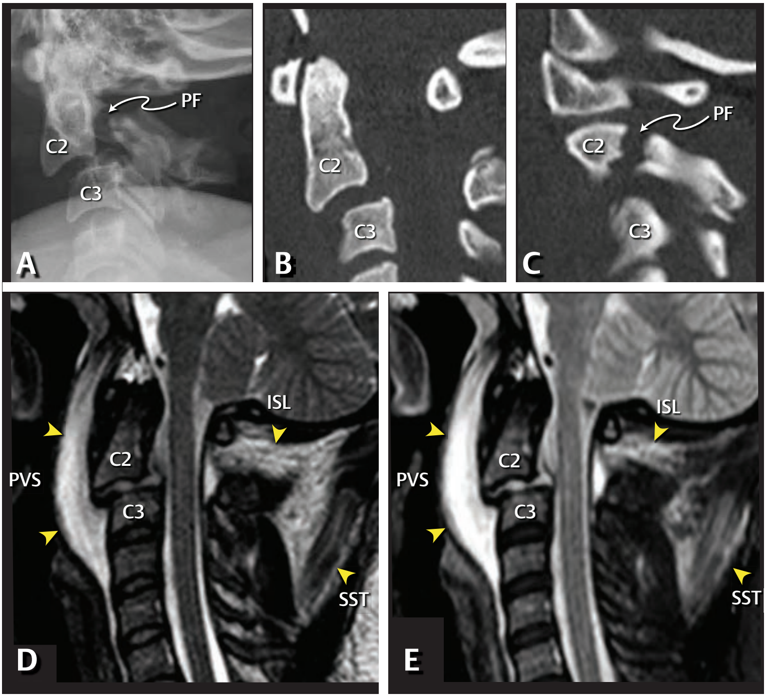

Fig. 70.3 Hangman's fracture Type II.
The amount of anterior displacement of C2 on C3 qualifies this as a Type II. Abnormal signal in the C2-3 disc on MRI indicates possible disc disruption.
Image: A: lateral C-Spine X-ray. B: sagittal midline CT scan, bone window. C: sagittal CT scan, left of midline through pars fracture, bone window. D: sagittal T2 MRI. E: sagittal STIR MRI.
Legend: PF = pars fracture. *Yellow arrowheads* indicate abnormal signal on MRI in the prevertebral space (PVS), interspinous ligament (ISL) between C2 and C3, and in the supraspinous tissues (SST).

Stable fractures (Levine Types I or IA, or Francis Grades I or II)

Treat with immobilization (Aspen or Philadelphia collar[64 (p 2326)] or cervicothoracic orthosis (CTO) (e.g., SOMI) is usually adequate) × 3 months.[55] Halo-vest may be needed in unreliable patients or for combination C1–2 fractures. Schneider reported 50 cases of Type I fracture treated with non-halo fixation, only 1 was taken to surgery and was found to already be fused.

Unstable fractures

Levine Type II

Reduce with gentle *cervical traction* (most reduce with ≤ 30 lbs[55]) with the head in slight extension (preferably in halo ring) under close X-ray monitoring to prevent "iatrogenic hanging" in cases with ligamentous instability.[56] Place in halo vest × 3 months. Follow patients with serial X-rays. Stabilize surgically if fracture moves.

Type II fractures with ≤ 5 mm of subluxation and angulation < 10°

Once reduced, apply halo-vest and begin to mobilize (usually within 24 hrs of injury). Verify that immobilization is adequate in the halo with upright lateral C-spine X-ray, operate if inadequate. After 8–12 weeks, change to Philadelphia collar or CTO until fusion is definitely complete (usually 3–4 months).

Type II fractures with > 5 mm subluxation or ≥ 10° of angulation

Surgical fusion in these patients is recommended because of the following concerns:

1. risk of settling if immediately mobilized in halo-vest
2. healing with significant angulation may result in chronic pain
3. if not reduced, the gap may be too large for bony bridging using traction alone

Alternatively, cervical traction can be maintained for ≈ 4 weeks and then reduction should be reassessed 1 hour after removing weight from traction, and if stable, again 24 hours after mobilizing in a halo vest. If unstable, return to traction and repeat trial at 5 & 6 weeks. If still unstable at 6 weeks, surgical fusion is recommended.[55]

Levine Type IIA

✖ Traction will accentuate the deformity.[55] Fractures should be reduced by immediate placement in halo vest (bypassing traction) with extension and *compression* applied. Halo-vest immobilization × 3 months produces ≈ 95% union rate.

Levine Type III

✖ Reduction with traction may be dangerous with locked facets. ORIF is recommended.[27] MRI prior to surgery is recommended to assess the C2–3 disc. Can follow ORIF with halo-vest for the fracture, or can fuse at the same time as ORIF.

Surgical treatment

Indications

Few patients have indications for surgical treatment of HF, and include those with:

1. inability to reduce the fracture (includes most Levine Type III & some Type II)
2. failure of external immobilization to prevent movement at fracture site
3. traumatic C2–3 disc herniation with compromise of the spinal cord[65]
4. established non-union: evidenced by movement on flexion-extension film (p. 1145) [56]; all failures of nonoperative treatment had displacement > 4 mm[27]

Hangman’s fractures likely to need surgery[57]:

1. Levine Type II or III
2. or Francis grade II, IV, or V
3. or if either:
   a) anterior displacement of C2 VB > 50% of the AP diameter of the C3 VB
   b) or if angulation produces widening of either the anterior or posterior borders of the C2–3 disc space > the height of the normal C3–4 disc below

Surgical options

For the infrequent patient who needs surgery for a hangman’s fracture. The fracture is either transfixed (osteosynthesis) or fusion across the fracture must be done as outlined here:

1. fusion techniques:
   a) posterior approach:
      - C1–2 posterior wiring and fusion (e.g., using interspinous fusion technique of Dickman and Sonntag (p. 1783)) is an option only if all the following are intact: C2–3 disc, C2–3 joint capsules and posterior arch of C1. Rationale: this procedure unites C1 to the posterior fracture fragment of C2 which is still linked to C3 by the facet joints (posterior to the fracture), while the portion of C2 anterior to the fracture is still linked to C3 through the C2–3 disc. This technique preserves motion between C2 & C3.
      - C1–3 fusion using C1 lateral mass screws (p. 1780) & C3 lateral mass screws connected with rods (skipping C2)
      - occiput-C3 fusion: may be used if C1 is also damaged (skipping C1 & C2)
   b) anterior C2–3 discectomy[56] with fusion. Optional anterior plating or zero-profile graft/plate. Performed via a transverse anterior cervical incision midway between the angle of the jaw and the thyroid cartilage[60,65]
      - preserves more motion by excluding C1
      - this approach is also recommended for established nonunion[56]
      - not optimal for Levine Type III requiring ORIF for locked facets
      - also used when at least a partial reduction cannot be achieved
      - technique: for special considerations for approach to the C2–3 junction, see Anterior approaches to the cervical spine (p. 1771) (cannot be performed in some short & thick necks). The services of a head and neck surgeon for the approach is an option

2. osteosynthesis: screw placement from posterior approach through the C2 pedicle across the fracture fragment.[55(p 443)] Not recommended for established nonunion. The fracture must be reduced before the screw holes are drilled[66] (the fracture may be reduced by patient positioning, and can be assisted by pulling posteriorly on the ring or C1 e.g., using a cable looped through C1[67]). Screw entry point and trajectory are similar to the technique for C2 pedicle screws (p. 1781). The posterior fracture fragment may be overdrilled with a 3.5 mm drill. A "top hat" or washer is placed in the hole and a 2.7 mm drill is used to drill the VB. Screw length: 30–35 mm for average adults. An alternative to overdrilling is to use a lag screw with 20 mm unthreaded portion (e.g., Depuy ASIF orthopedic screws are available in 4.5 mm diameter at 30 mm length with 16 mm unthreaded portion, which is close).

Treatment endpoint

Plain X-rays should show trabeculation across the fracture site or interbody fusion of C2 to C3. Flexion-extension lateral radiographs should show no movement at the fracture site.

70.5.4 Odontoid fractures

General information

Key concepts

- 10–15% of C-spine fx. Can occur in older patients with minor trauma (e.g., ground level fall), or in younger patients typically following MVA, falls from a height, skiing…
- classification: Anderson & D'Alonzo (▶ Table 70.10). Type II (at base) is the most common
- may be fatal at time of injury, most survivors are intact. Neck pain is common
- Treatment: surgery is considered for:
  - Type II if age > 50 yrs
  - Type IIA
  - or Type II & III if displacement ≥ 5 mm or if alignment cannot be maintained with halo

In young individuals, significant force is required to produce an odontoid fracture, usually sustained in a motor vehicle accident (MVA), a fall from a height, a skiing accident, diving head-first into shallow water, etc. In patients > 65 years of age, simple ground level falls (GLF) with head trauma may be sufficient to fracture the dens as a result of disproportionate reduction in bone density at the base of the odotoid relative to the rest of C2.[68] Odontoid fractures comprise ≈ 10–15% of all cervical spine fractures,[69] but are the most common cervical spine fracture in patients > 65 years old.[70] They are easily missed on initial evaluation, especially since significant associated injuries are frequent and may mask symptoms. Pathologic fractures can also occur, e.g., with metastatic involvement (p. 1679).

Flexion is the most common mechanism of injury, with resultant anterior displacement of C1 on C2 (atlantoaxial subluxation). Extension only occasionally produces odontoid fractures, usually associated with posterior displacement.

Classification

The Anderson and D'Alonzo[71] classification (▶ Fig. 70.4 and ▶ Table 70.10) is the most widely used.

▶ **Type I fractures.** Very rare. Result from avulsion of the odontoid tip due to traction on the alar ligament. Originally described as having an angulated orientation.[71] Once considered stable, they may not occur as an isolated fracture and may be a manifestation of atlantooccipital dislocation.[73] Also, it may be a marker for possible disruption of the transverse ligament,[74] which may result in atlanto-axial instability.

▶ **Type II odontoid fractures.** Nonunion rate is higher than with types I & III. Proposed explanations for this include:

1. the base of the odontoid has a watershed blood supply between arteries supplying the tip and those supplying the body[75]
2. paucity of cancellous bone and small surface area of the neck of the odontoid[76]
3. ligaments attached to the odontoid tend to distract and displace it

Table 70.10 Anderson and D'Alonzo classification of odontoid fractures

Type	Characteristics	Stability
I	through tip (above transverse ligament), rare	unstable[a]
II	through base of neck. The most common dens fracture	usually *unstable*
IIA	similar to type II, but with large bone chips at fracture site,[72] comprise ≈ 3% of type II odontoid fractures. Diagnosed by plain radiographs and/or CT	usually *unstable*
III	through body of C2 (usually involves marrow space). May involve superior articular surface	usually stable

[a] controversial, see text

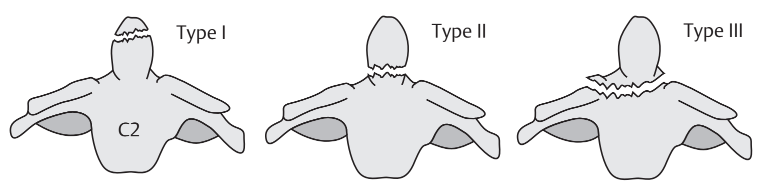

Fig. 70.4 Anderson and D'Alonzo classification of odontoid fractures (AP view).

Radiographic evaluation

A type III odontoid fracture may be misinterpreted as type II on sagittal CT (see "A" in ▶ Fig. 70.5) because the fracture may appear to lie just above the VB. The coronal view more readily demonstrates the relationship of the fracture to the VB.

On plain x-rays, type II fractures are usually better appreciated on AP view (including open mouth odontoid view).

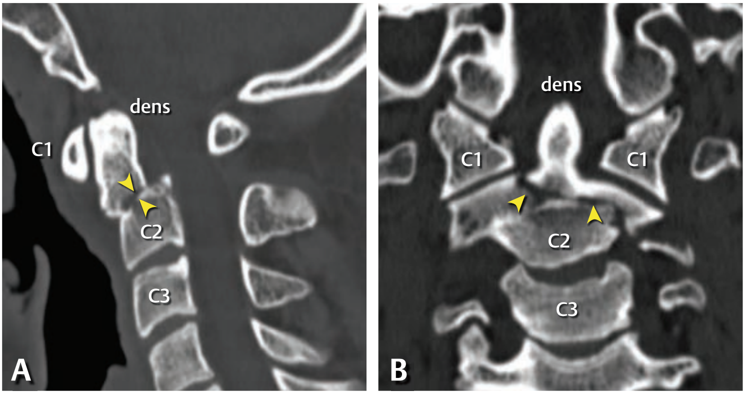

Fig. 70.5 Odontoid type III fracture (*yellow arrowheads*) wiith anterior displacement.
Image: CT bone windows, A: midline sagittal, B: coronal.

Signs and symptoms

The frequency of fatalities at the time of the accident resulting directly from odontoid fractures is unknown, it has been estimated as being between 25–40%.[77] 82% of patients with Type II fractures in a review of 7 reports in the literature were neurologically intact, 8% had minor deficits of scalp or limb sensation, and 10% had significant deficit (ranging from monoparesis to quadriplegia).[78] Type III fractures are rarely associated with neurologic injury.

Common symptoms are high posterior cervical pain, sometimes radiating in the distribution of the greater occipital nerve (occipital neuralgia). Almost all patients with high posterior cervical pain will also have paraspinal muscle spasm, reduced range of motion of the neck, and tenderness to palpation over the upper cervical spine. A very suggestive finding is the tendency to support the head with the hands when going between the upright and supine position. Paresthesias in the upper extremities and slight exaggeration of muscle stretch reflexes may also occur. Myelopathy may develop in patients with nonunion (p. 1174).

Treatment

Practice guidelines

Practice guidelines are shown below. Details appear in the following sections.

Practice guideline: Management of isolated odontoid fractures

- Level II[38]: isolated Type II odontoid fractures in adults ≥ 50 years of age should be considered for surgical stabilization & fusion
- Level III[38]
  - Nondisplaced type I, II & III fractures may be managed initially with external cervical immobilization, recognizing that type II odontoid fractures have a higher rate of nonunion
  - Type II & III: consider surgical fixation for:
    a) dens displacement ≥ 5 mm
    b) or Type IIA fracture (comminution of fracture)
    c) or inability to maintain or achieve alignment with external immobilization
  - For surgical intervention, either an anterior or posterior approach may be used

Immobilization

For those not meeting surgical indications, 10–12 weeks of immobilization as suggested in ▶ Table 70.11 is recommended. There is no Class I medical evidence comparing immobilization options.

Halo vest: fusion rate = 72%,[79] appears superior to an SOMI. If a halo is used, obtain supine and upright lateral C-spine X-rays in the halo. If there is movement at the fracture site, then surgical stabilization is recommended.

Rigid collar[79,80]: fusion rate = 53%.

In patients who are poor surgical candidates, there is theoretical and anecdotal rationale to consider calcitonin therapy (p. 1211) in conjunction with a rigid cervical orthosis.[81]

Table 70.11 Immobilization for odontoid fractures

Fracture type	Option
Type I	collar, halo
Type II[a]	halo, collar[b]
Type IIA[a]	halo[a]
Type III[a]	collar[b], halo

[a] consider surgery for these, use indicated brace when surgery not deemed appropriate
[b] a CTO (cervicothoracic orthosis) provides better immobilization against flexion and rotation than a collar or an SOMI

Type I

So rare that meaningful analysis is difficult. If there is associated atlanto-axial instability, surgical fusion may at times be necessary.

Type II

General information

Treatment remains controversial. No agreement has been reached after many attempts to identify factors that will predict which type II fractures are most likely to heal with immobilization and which will require operative fusion. Critical review of the literature reveals a paucity of well-designed studies. A wide range of nonunion rates with immobilization alone (5–76%) is quoted: 30% is probably a reasonable estimate for overall nonunion rate, with 10% nonunion rate for those with displacement < 6 mm.[79] Possible key factors in predicting nonunion include:

1. degree of displacement: probably the most important factor
   a) some authors contend that displacement > 4 mm increases nonunion[71,82]
   b) some use ≥ 6 mm as the cutoff, citing a 70% nonunion rate[62] for these regardless of age or direction of displacement
2. age:
   a) children < 7 yrs old almost always heal with immobilization alone
   b) some feel that there is a critical age above which the nonunion rate increases, and the following ages have been cited: age > 40 yrs (possibly ≈ doubling the nonunion rate),[82] age > 55 yrs,[83] age > 65 yrs,[84] yet others do not support increasing age as a factor[79]

Indications for surgery for odontoid type II fractures

Given the above, there can be no hard and fast rules. The following is offered as a guideline (also, see above).

70

★ Surgical treatment (instead of external immobilization) is recommended for odontoid type II fractures in patients ≥ 7 years of age with any of the following:

1. displacement ≥ 5 mm
2. instability at the fracture site in the halo vest (see below)
3. age ≥ 50 years: increases nonunion rate (with halo) 21-fold[85]
4. nonunion (see ▶ Table 70.12 for radiographic criteria) including firm fibrous union,[86] especially if accompanied by myelopathy[59]
5. disruption of the transverse ligament: associated with delayed instability[36]

Surgical options

1. odontoid compression screw (p. 1779): appropriate for acute type II fractures with transverse ligament intact and attached
2. C1–2 arthrodesis (p. 1778): options include wiring/fusion, transarticular screws, halifax clamps…

Type IIA

Early surgery is recommended for all type IIA fractures.[72]

Type III

≈ 90% heal with external immobilization (and analgesics) if adequately maintained for 8–14 weeks.[62] Halo-vest brace is probably best,[80] fusion rate ≈ 100% in 1 series.[79] Rigid collar: fusion rate = 50–70%; if used, monitor the patient with frequent C-spine X-rays to rule out nonunion.

Surgical treatment options

See Atlantoaxial fusion (C1–2 arthrodesis) (p. 1778) and Anterior odontoid screw fixation (p. 1775) for surgical options and operative details.

Nonunion

The radiographic criteria for nonunion are shown in ▶ Table 70.12.

Table 70.12 Radiographic criteria of nonunion of odontoid fractures

- defect in the dens with contiguous sclerosis of both fragments (vascular pseudarthrosis)
- defect in the dens with contiguous resorption of both fragments (rarefying osteitis or atrophic pseudarthrosis)
- defect in the dens with definite loss of cortical continuity
- movement of dens fragment demonstrated on flexion-extension X-rays

The most common symptom of nonunion is continued high posterior cervical pain beyond the time that the brace is removed. Late myelopathy can develop in as many as 77% of mobile nonunions[77,87] as a result of motion and soft tissue proliferation around the unstable fracture site.

Os odontoideum

General information

A separate bone ossicle of variable size with *smooth* cortical borders separated from a foreshortened odontoid peg, occasionally may fuse with the clivus (▶ Fig. 70.6). May mimic Type 1 or 2 odontoid fracture. Etiology is debated with evidence to support both of the following (diagnosis & treatment do not depend on which etiologic theory is correct):

1. congenital: developmental anomaly (nonunion of dens to body of axis). However, does not follow known ossification centers (▶ Fig. 12.5) and has been demonstrated in 9 patients with previously normal odontoid processes[88]
2. acquired: postulated to represent an old nonunion fracture or injury to vascular supply of developing odontoid[88,89]

Two anatomic types:

1. orthotopic: ossicle moves with the anterior arch of C1
2. dystopic: ossicle is functionally fused to the basion. May sublux anterior to the C1 arch

True os odontoideum is rare. Ossiculum terminale: nonunion of the apex at the secondary ossification center, is more common.

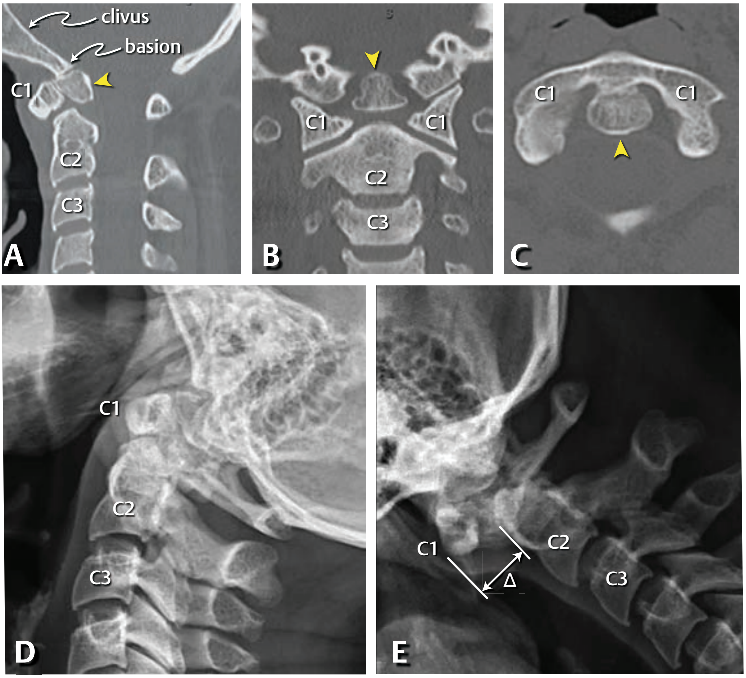

Fig. 70.6 Os odontoideum (*yellow arrowheads*).
Image: CT bone windows, A: sagittal; B: coronal, C: axial.
Lateral cervical spine X-rays, D: extension; E: flexion (note the forward displacement Δ of C1 upon flexion).

Presentation

Main groups identified in the literature[90]:

1. occipitocervical/neck pain
2. myelopathy: further subdivided[88]
   a) transient myelopathy: common following trauma
   b) static myelopathy
   c) progressive myelopathy
3. intracranial signs or symptoms: from vertebrobasilar ischemia
4. incidental finding

Most patients are neurologically intact and present with atlantoaxial instability, which may be discovered incidentally. Many symptomatic and asymptomatic patients have been reported with no new problems over many years of follow-up.[91] Conversely, cases of precipitous spinal cord injury after seemingly minor trauma have been reported.[92]

Σ: Natural history of os odontoideum

The natural history is variable, and predictive factors for deterioration, especially in asymptomatic patients, have not been identified.[93]

Evaluation

Practice guideline: Diagnosis of os odontoideum

Level III[94]

- recommended: the following plain C-spine X-rays: AP, open-mouth odontoid, lateral (static & flexion-extension) with or without tomography (CT or plain) and/or MRI of craniocervical junction

It is critical to R/O C1–2 instability. However, myelopathy does not correlate with the degree of C1–2 instability. An AP canal diameter < 13 mm does correlate with the presence of myelopathy.

Treatment

Regardless of whether os odontoideum is congenital or an old nonunion fracture, immobilization is unlikely to result in fusion. Therefore, when treatment is elected, surgery—usually atlantoaxial arthrodesis (p. 1778)—is required.

Practice guideline: Management of os odontoideum

Level III[94]

- patients without neurologic signs or symptoms:
  - may be followed with clinical & radiographic surveillance
  - or posterior C1–2 fusion may be done
- patients with neurologic signs or symptoms or C1–2 instability: posterior C1–2 internal fixation and fusion
- if surgery is done: if rigid internal instrumentation is not used, then post-op halo immobilization is recommended (e.g., following posterior wiring & fusion)
- for patients with irreducible cervicomedullary compression and/or evidence of associated occipitoatlantal instability: occipital-cervical fusion ± C1 laminectomy
- for patients with irreducible cervicomedullary compression, consider ventral decompression

70.5.5 Miscellaneous C2 fractures

Comprise ≈ 20% of C2 fractures.[27] Includes fractures of spinous process, lamina, facets, lateral mass or C2 vertebral body. Fractures of spinous process or lamina may be treated with Philadelphia collar or cervicothoracic orthosis (CTO). Fractures which compromise the anterior or middle columns (i.e., fractures of facets, C2 body, or lateral mass) require CTO or halo-vest if nondisplaced, or halo if displaced.

Practice guideline: Management of fractures of the axis (C2) body

Level III[38,63]:

- fractures may initially be managed with external immobilization in most cases (halo or collar)
- surgical stabilization should be considered in cases of:
  a) severe ligamentous instability
  b) or inability to establish or maintain alignment with external immobilization
- evaluate for vertebral artery injury in cases of comminuted fracture of the axis body

70.6 Combination C1 & C2 injuries

70.6.1 General information

Combination C1–2 injuries are relatively common and may imply more significant structural and mechanical injury than isolated C1 or C2 fractures. The frequency of C2 fractures in C1–2 combination injuries is shown in ▶ Table 70.13. 5–53% of patients with Type II or III odontoid fractures and 6–26% of hangman's fractures have an associated C1 fracture.[95]

Table 70.13 Accompanying C2 injuries

Injury	%
Type II dens fracture	40
Type III dens fracture	20
hangman's fracture	12
other	28

70.6.2 Treatment

Practice guideline: Treatment of combination atlas and axis fractures

Level III[95]

1. recommended: base treatment primarily on the type of C2 injury
2. recommended: external immobilization of most C1–2 fractures
3. consider surgical stabilization for these situations. **Note**: loss of integrity of the C1 ring may necessitate modification of the surgical technique; these injuries are potentially unstable: see Axis (C2) fractures (p. 1165):
   a) C1-Type II odontoid combination fractures with an ADI ≥ 5 mm
   b) C1-hangman's combination fractures with C2–3 angulation ≥ 11°

Treatment options are summarized in ▶ Table 70.14.[95]

Table 70.14 Treatment options for combination C1–2 injuries

Injury	Treatment options
C1 + hangman's	
• stable	collar, halo, surgery[a]
• unstable (C2–3 angulation ≥ 11°)	halo, surgery
C1 + Type II odontoid fracture	
• stable (ADI[a] < 5 mm)	collar, halo, surgery
• unstable (ADI ≥ 5 mm)	halo, surgery
C1 + Type III odontoid fracture	halo
C1 + miscellaneous C2	collar, halo

[a] abbreviations: ADI = atlantodental interval; surgery = surgical fixation & fusion

70.6.3 Outcome

Only 1 nonunion (C1 + Type II odontoid, treated initially with halo). No new neuro deficits.

71 Subaxial (C3 through C7) Injuries / Fractures

71.1 Classification systems

71.1.1 General information

Various systems have been proposed to help assess stability and/or guide management. The Allen-Ferguson system (p. 1182) is based on the mechanism of injury. Attempts at quantifying biomechanical stability include the White and Panjabi system (p. 1182) and the more recent subaxial injury classification (SLIC) (see below). Measurements for spine injuries are based on methods outlined by Bono et al.[1]

Practice guideline: Subaxial cervical spine injury classification

Level I[2]

- Use the Subaxial Injury Classification (SLIC) and severity scale for SCI (see below)
- Classify the stability and fracture pattern using the Cervical Spine Injury Severity Score (CSISS): the CSISS is somewhat complicated and may be better suited to clinical trials than daily practice (see reference[2])

71.1.2 Spine Trauma Study Group subaxial cervical spine injury classification (SLIC)

▶ **General information.** The subaxial injury classification (SLIC)[3] is shown in (▶ Table 71.1) and assesses injuries to the disco-ligamentous complex (DLC) in addition to neurologic and bony injuries. Inter-rater reliability intraclass correlation coefficient is 0.71.

Table 71.1 Subaxial injury classification (SLIC)[3]

Injury (rate *the most severe injury* at that level)		**Points**	**Score**
Morphology	no abnormality	0	**(0 - 4)**
	simple compression (compression fx, endplate disruption, sagittal or coronal plane VB fx)	1	
	burst fracture	2	
	distraction (perched facet, posterior element fx)	3	
	rotation/translation (facet dislocation, teardrop fx (p. 1184), advanced compression injury, bilateral pedicle fx, floating lateral mass (p. 1192). Guidelines: relative axial rotation ≥ 11°[4] or any translation not related to degenerative causes	4	
Discoligamentous complex (DLC)	intact	0	**(0 - 2)**
	indeterminate (isolated interspinous widening with < 11° relative angulation & no abnormal facet alignment, ↑ signal on T2WI MRI in ligaments...)	1	
	disrupted (perched or dislocated facet, < 50% articular apposition, facet diastasis > 2 mm, widened anterior disc space, ↑ signal on T2WI MRI through entire disc...)	2	
Neurologic status	intact	0	**(0 - 3)**
	root injury	1	
	complete spinal cord injury	2	
	incomplete spinal cord injury	3	
	● continuous cord compression with neuro deficit	+ 1	**(+ 1)**
SLIC score → TOTAL			**(0 - 10)**

► **DLC integrity.**[3] The DLC includes: anterior longitudinal ligament (the strongest component of the anterior DLC), posterior longitudinal ligament, ligamentum flavum, facet capsule (the strongest component of the posterior DLC), interspinous and supraspinous ligaments. The DLC is the hardest SLIC parameter to evaluate. Largely inferred indirectly from MRI findings. Healing is less predictable than bone healing in the adult. More data needs to be accrued before this parameter can be reliably quantified.

► **Management based on the total SLIC score is shown in ► Table 71.2.**

Table 71.2 Management based on total SLIC score

SLIC score	Management
1–3	non surgical
4	not specified
≥ 5	surgical

► **A given injury can be described using the SLIC as follows:**
1. spinal level
2. *SLIC morphology* (from ► Table 71.1): use the most severe injury type at this level
3. description of bony injury: e.g., fracture or dislocation of transverse process, pedicle, endplate, superior or inferior articular process, lateral mass…
4. *SLIC DLC status* (from ► Table 71.1) with descriptors: e.g., herniated disc…
5. *SLIC neurologic status* (from ► Table 71.1)
6. confounders: e.g., presence of ankylosing spondylitis, DISH, osteoporosis, previous surgery, degenerative disease…

71.1.3 Cervical spine injury classification on the basis of mechanism of trauma

A modification of the Allen-Ferguson system[5] divides cervical spine fracture-dislocations into 8 major groups based on the dominant loading force and neck position at the time of injury as shown in ► Table 71.3. Grades of severity within each group are described, and any of these fractures may also be associated with damage from rotatory loads.

Details on some of these fracture types are provided in the following sections.

Table 71.3 Examples of types of cervical spine injuries[a]

Major loading force	Acting alone	With compression	With distraction
Flexion (p. 1183)	unilateral or bilateral facet dislocation (p. 1186)	• anterior VB fx with kyphosis • disruption of interspinous ligament • teardrop fx (p. 1184)	• torn posterior ligaments (may be occult) • dislocated or locked facets (p. 1186)
Extension[b] (p. 1191)	fractured spinous process and possibly lamina[b]	fracture through lateral mass or facet[b], including horizontalization of facet (p. 1191)	disruption of ALL with retrolisthesis of superior vertebrae on inferior one[b]
Neutral position		burst fracture (p. 1183)	complete ligamentous disruption (very unstable)

[a]abbreviations: ALL = anterior longitudinal ligament; VB = vertebral body, fx = fracture; numbers in parentheses are page numbers for that topic
[b]any of the extension injuries may produce SCIWORA in young patients, or central cord syndrome in the presence of stenosis

71.1.4 Stability model of White and Panjabi

Guidelines for determination of clinical instability (p. 1118) of the subaxial cervical spine published by White and Panjabi[6 (p 314)] are shown in ► Table 71.4. In general, all else being equal, compromise of anterior elements produces more instability in extension, whereas compromise of the posterior elements produces more instability in flexion (important in patient transfers and immobilization). NB: certain conditions such as ankylosing spondylitis (p. 1365) may cause an otherwise stable injury to be unstable.

Table 71.4 Panjabi and White criteria for instability of the mid & lower C-spine (Panjabi and White)[6])

Item		**Points[a]**	**Score**
anterior elements[b] destroyed or unable to function		2	**(0 | 2)**
posterior elements[b] destroyed or unable to function		2	**(0 | 2)**
positive stretch test[c]		2	**(0 | 2)**
spinal cord damage		2	**(0 | 2)**
nerve root damage		1	**(0 | 1)**
abnormal disc narrowing		1	**(0 | 1)**
developmentally narrow spinal canal, either • sagittal diameter < 13 mm, OR • Pavlov ratio[d] < 0.8		1	**(0 | 1)**
dangerous loading anticipated[e]		1	**(0 | 1)**
Evaluation of either one of the following 2 X-rays			
1) neutral position cervical spine X-rays OR	**2) flexion-extension cervical spine X-rays**		
• sagittal plane displacement > 3.5 mm or 20%	• sagittal plane translation > 3.5 mm or 20%	2	**(0 | 2)**
• relative sagittal plane angulation > 11°	• sagittal plane rotation > 20°	2	**(0 | 2)**
Range: 0 to 16; unstable if ≥ 5 → TOTAL			**(0 - 16)**

[a] if there is inadequate information for any item, add half of the value for that item to the total

[b] in the C-spine, posterior elements = anatomic components posterior to the posterior longitudinal ligament

[c] stretch test: apply incremental cervical traction loads of 10 lbs q 5 mins up to 33% body wt. (65 lbs max). Check X-ray and neuro exam after each change. Positive if increase in separation > 1.7 mm or increase angulation > 7.5° on X-ray or change in neuro exam. This test is contraindicated if obvious instability

[d] Pavlov ratio = the ratio of (distance from the midlevel of the posterior VB to the closest point on the spinolaminar line): (the AP diameter of the middle of the VB)

[e] e.g., heavy laborers, contact sports athletes, motorcyclists

Stretch test: The cervical stretch test may be helpful in cases where stability is difficult to determine based on other factors. It may also be useful in detecting instability in cases such as an athlete with no obvious bony or ligamentous disruption. It is performed by applying graduated cervical traction with the patient lying supine on an X-ray table. Serial neurologic exams and lateral radiographs are performed as outlined in the footnote of ▶ Table 71.4.

71.2 Clay shoveler's fracture

Avulsion of spinous processes (usually C7) first described in Perth, Australia (pathomechanics: during the throwing phase of shoveling, clay may stick to the shovel jerking the trapezius and other muscles which are attached to cervical spinous processes).[7] Can also occur with: whiplash injury,[8] injuries that jerk the arms upwards (e.g., catching oneself in falling), neck hyperflexion, or a direct blow to the spinous process.

This fracture is stable, and by itself poses little risk. If the patient is intact, they should have further study (flexion-extension C-spine X-rays or CT scan through the affected level) to R/O other occult fractures. A rigid collar is used PRN pain.

71.3 Vertical compression injuries

In order to apply a purely compressive force to the cervical spine without flexion or extension, reversal of the normal cervical lordosis is required, as may occur in a slightly flexed posture. Burst fractures are the most common result, with the possibility of retropulsion of bone into the spinal canal with neurologic deficit.

71.4 Flexion injuries of the subaxial cervical spine

71.4.1 General information

Constitute up to 15% of cervical spine trauma. Common causes include: MVAs, falls from a height, and diving into shallow water.[9]

71.4.2 Compression flexion injuries

The classic diving injury is the prototypical example. Posterior element fractures occur in up to 50% of compression flexion injuries.[10] Although flexion-compression injuries do distract the posterior elements to some degree, most do not produce posterior ligamentous injuries. Subtypes of compression-flexion fractures include: teardrop fractures (see below), quadrangular fractures (p. 1185).

Treatment: mild cervical compression fractures without neurologic deficit or retropulsion of bone into the spinal canal are usually treated with a rigid orthosis until X-rays show healing has occurred (usually 6–12 wks). Stability is assessed with flexion-extension views (p. 1145) before completely discontinuing the brace. More severe compression fractures heal in a halo brace with ≈ 90% rate of ankylosing fusion.

71.4.3 Teardrop fractures

General information

Originally described by Schneider & Kahn.[11] Results from hyperflexion or axial loading at the vertex of the skull with the neck flexed (eliminating the normal cervical lordosis)[12] (often mistakenly attributed to hyperextension because of the retrolisthesis). Two forces are involved: 1) compression of the anterior column, and 2) tension on DLC. There are varying degrees of severity. In its most severe form, the injury consists of complete disruption of all of the ligaments, the facet joints and the intervertebral disc[13] and ≥ 3 mm of posterior displacement of the body into the canal. As originally described, an important feature is displacement of the inferior margin of the fractured vertebral body posteriorly into the spinal canal.[11] Usually unstable.

Seen in ≈ 5% of patients in a large series of patients with X-ray evidence of cervical spine trauma.[14] Patients are often quadriplegic, although some may be intact and some may have anterior cervical cord syndrome (p. 1135).

Findings

Possible associated injuries and radiographic findings include[13,15] (▶ Fig. 71.1):

1. a small chip of bone (the “teardrop”) just beyond the anterior inferior edge of the involved vertebral body (VB) on lateral cervical spine film
2. often associated with a fracture through the sagittal plane of the VB (sagittal split) which can almost always be seen on AP view (may be midline or off-center). Thin cut CT scan is more sensitive
3. a large triangular fragment of the anterior inferior VB
4. other fractures through the vertebral body may also occur
5. the fractured vertebra is usually displaced *posteriorly* on the vertebra below (also appreciated on oblique X-rays, ▶ Fig. 71.5). However, cases without retrolisthesis are also described[10]

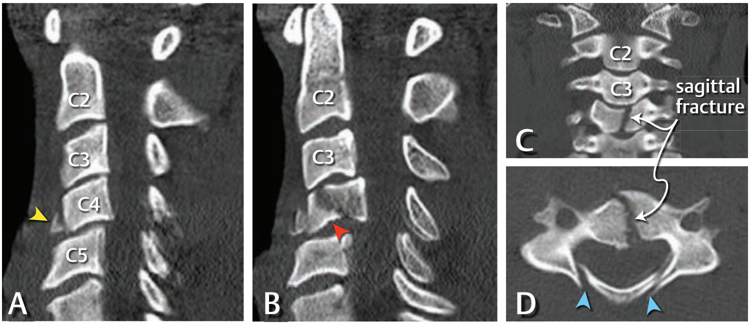

Fig. 71.1 Teardrop fracture of C4.
Image: CT bone windows, A: sagittal, showing the small chip of bone (the “teardrop”) (*yellow arrowhead*) and the posteriorly displaced VB; B: sagittal (adjacent to A), showing a large triangular fragment of the C4 VB (*red arrowhead*); C: coronal; D: axial through the C4 VB, showing the sagittally oriented fracture (there are also bilateral lamina fractures [*blue arrowheads*]—not part of the criteria for a teardrop fracture).

6. the fractured body is often wedged anteriorly (kyphosis), and may also be wedged possibly laterally
7. disruption of the facet joints which may be appreciated as separation of the joints on lateral X-ray, often unmasked by cervical traction
8. prevertebral soft-tissue swelling, see for measurements (p. 224)
9. narrowing of the intervertebral disc below the fracture (indicating disruption)

Distinguishing between teardrop fracture and avulsion fracture

Rationale: Teardrop fractures must be distinguished from a simple avulsion fracture which may also result in a small chip of bone off the anterior inferior VB, usually pulled off by traction of the anterior longitudinal ligament (ALL) in hyperextension. Although there may be disruption of the ALL in these cases, it does not usually cause instability.

Methodology: In a patient with a small bone chip off of the inferior anterior VB, a "teardrop" fracture needs to be ruled out. Determine if the following criteria are met:

- neurologically intact (because of the need for cooperation, this includes mental status, and excludes the inebriated or concussed patient)
- size of bone fragment is small
- no malalignment of vertebral bodies
- no evidence of VB fracture in sagittal plane on AP C-spine X-rays or on CT
- no posterior element fracture on X-ray or CT
- no prevertebral soft tissue swelling (p. 224) at level of fragment
- and no loss of vertebral body height or disc space height

If the above criteria are met, obtain flexion-extension C-spine X-rays (p. 1145). If no abnormal movement, discharge patient in rigid collar (e.g., Philadelphia collar), and repeat the films in 4–7 days (i.e., after the pain has subsided to be certain that alignment is not being maintained by cervical muscle spasm from pain), D/C collar if 2nd set of films is normal.

If the patient does not meet the above criteria, treat them as an unstable fracture and obtain a CT scan through the fractured vertebra to evaluate for associated fractures (e.g., sagittal plane fracture that may not be apparent on plain X-ray).

MRI assesses the integrity of the disc and gives some information about the posterior ligaments.

Treatment of teardrop fracture

If the disc and ligaments are intact (determined by MRI) then an option is to employ a halo brace until the fragment is healed (perform flexion-extension X-rays after removing the halo to rule out persistent instability). Alternatively, surgical stabilization may be performed, especially if ligamentous or disc injury is seen on MRI. When the injury is primarily posterior due to disruption of the posterior ligaments and facet joints, and if there is no anterior compromise of the spinal canal, then posterior fusion suffices (p. 1195). Severe injuries with canal compromise often require a combined anterior decompression and fusion (performed first) followed by posterior fusion typically using lateral mass screws and rods.

71.4.4 Quadrangular fractures

See reference.[16]

Four features:

1. oblique vertebral body (VB) fracture passing from anterior-superior cortical margin to inferior endplate
2. posterior subluxation of superior VB on the inferior VB
3. angular kyphosis
4. disruption of disc and anterior and posterior ligaments

Treatment:

May require combined anterior and posterior fusion.

71.5 Distraction flexion injuries

71.5.1 General information

Ranges from hyperflexion sprain (mild, see below) to minor subluxation (moderate) to bilateral locked facets (severe, see below). Posterior ligaments are injured early and are usually evidenced by widening of the interspinous distance (p. 224).

71.5.2 Hyperflexion sprain

A purely ligamentous injury that involves disruption of the posterior ligamentous complex without bony fracture. May be missed on plain lateral C-spine X-rays if they are obtained in normal alignment; requires flexion-extension views (p. 1145). Instability may be concealed when films are obtained shortly after the injury if spasm of the cervical paraspinal muscles splints the neck and prevents true flexion.[17] For patients with limited flexion, a rigid collar should be prescribed, and if the pain persists 1–2 weeks later the films should be repeated (including flexion-extension).

Radiographic signs of hyperflexion sprain[18] (X-rays may also be normal):

1. kyphotic angulation
2. anterior rotation and/or slight (1–3 mm) subluxation
3. anterior narrowing and posterior widening of the disc space
4. increased distance between the posterior cortex of the subluxed vertebral body and the anterior cortex of the articular masses of the subjacent vertebra
5. anterior and superior displacement of the superior facets (causing widening of the facet joint)
6. fanning (abnormal widening) of the interspinous space on lateral C-spine X-ray, or increased interspinous distance on AP; see Interspinous distances (p. 224)

71.5.3 Subluxation

Cadaver studies have shown that horizontal subluxation > 3.5 mm of one vertebral body on another, or > 11° of angulation of one vertebral body relative to the next indicates ligamentous instability[19,20] (▶ Table 71.4). Thus, if subluxation of ≤ 3.5 mm on plain films is seen, and there is no neuro deficit, obtain flexion-extension films; see Flexion-extension cervical spine X-rays (p. 1145). If no abnormal movement, remove cervical collar.

71.5.4 Locked facets

General information

Severe flexion injuries can result in locked facets (AKA "sprung" facets AKA "jumped" facets) with reversal of the normal "shingled" relationship between facets (normally the inferior facet of the level above is posterior to the superior facet of the level below). Involves disruption of facet capsule. Facets may be fractured.

Facets that have not completely locked but have had significant ligamentous disruption allowing distraction with the tip of the inferior facet positioned on the apex of the superior facet below are known as "perched facets" (▶ Fig. 71.2).

Flexion + rotation → unilateral locked facets. Hyperflexion → bilateral locked facets.

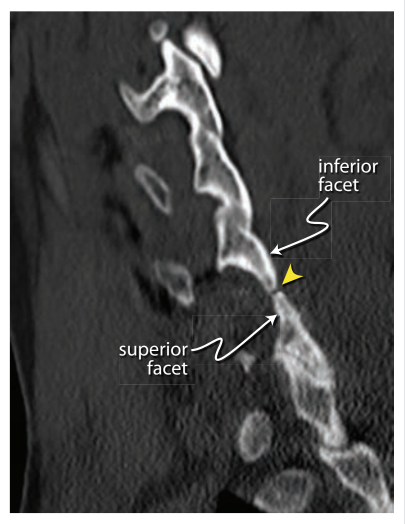

Fig. 71.2 Perched facet (*yellow arrowhead*).
Image: sagittal CT through the facet joints in a patient with previous fusion above the perched facet level.

▶ **Unilateral locked facets.** Comprise 6–10% of cervical spine injuries.[21] 25% of patients are neurologically intact, 37% have root deficit, 22% have incomplete cord injuries, and 15% are complete quadriplegics.[22]

▶ **Bilateral locked facets.** Occurs with disruption of ligaments of apophyseal joints, ligamentum flavum, longitudinal and interspinous ligaments, and the anulus. Rare. Most common at C5–6 or C6–7. 65–87% have complete quadriplegia, 13–25% incomplete, ≤ 10% are intact. Adjacent fractures (VB, facet, lamina, pedicle…) occur in 40–60%.[5,23] Nerve root deficits may also occur.

Diagnosis

Both unilateral locked facets (ULF) and bilateral locked facets (BLF) will produce subluxation: BLF poduces anterolisthesis, ULF produces a *rotatory* subluxation and usually a milder anterolisthesis.

▶ **CT. Sagittal CT:** usually the optimal modality to identify locked facets. The inferior facet of the superior level will be located anterior to the superior facet of the inferior level (opposite of normal) (▶ Fig. 71.3).

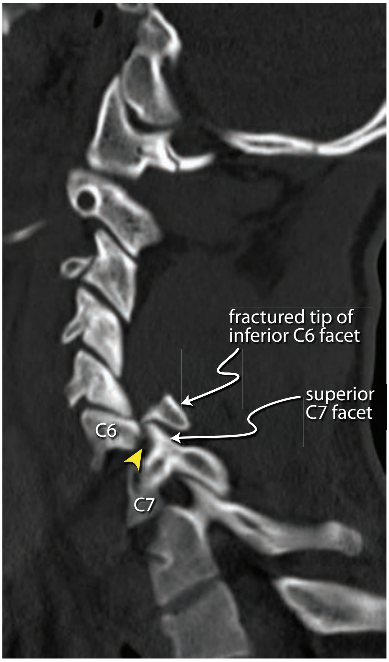

Fig. 71.3 Unilateral locked facet, left C6-7 (*yellow arrowhead*).
The C6 inferior facet is fractured with the tip displaced posteriorly.
Image: sagittal CT scan through the facet joints.

Axial CT: "naked facet sign": the articular surface of the facet will be seen with the appropriate articulating mate either absent or on the wrong side of the facet (▶ Fig. 71.4). With ULF, CT also demonstrates the rotation of the level above anteriorly on the level below on the side of the locked facet.

▶ **C-spine X-rays. BLF:** Usually produces > 50% subluxation on lateral C-spine X-ray.
ULF: Often missed on plain cervical spine X-rays because of relatively subtle findings.
✖ Beware of mimic (congenital absence of cervical pedicle - see below)

1. **AP X-ray:** spinous processes above the subluxation rotate to the same side as the locked facet (with respect to those below)
2. **lateral X-ray:** "bow-tie sign" (left & right facets at the level of the injury are side-by-side instead of the normal superimposed position[22]). Subluxation usually < 25% may be seen. Disruption of the posterior ligamentous complex may produce widening of the interspace between spinous processes

Note the anterior subluxation of C4 on C5, and the slight retrolisthesis of C5 on C6.

► **MRI.** Should be performed when possible to rule out traumatic disc herniation (found in 80% of BLF)[24] which may change the choice of approach (anterior vs. posterior) and is a contraindication to attempting closed reduction.

► **CTA.** Should be performed when possible because of the small chance of vertebral artery injury.

► ✖ **MIMIC: Congenital absence of a cervical pedicle.** Caution. This rare condition may mimic a unilateral locked facet (ULF) especially when discovered following trauma. C6 is the most common reported level.[25] The facet positions may be reversed from normal, as occurs in a locked facet.[26] It is almost always unilateral.[27]

A triad of findings has been described[28] (► Fig. 71.6):

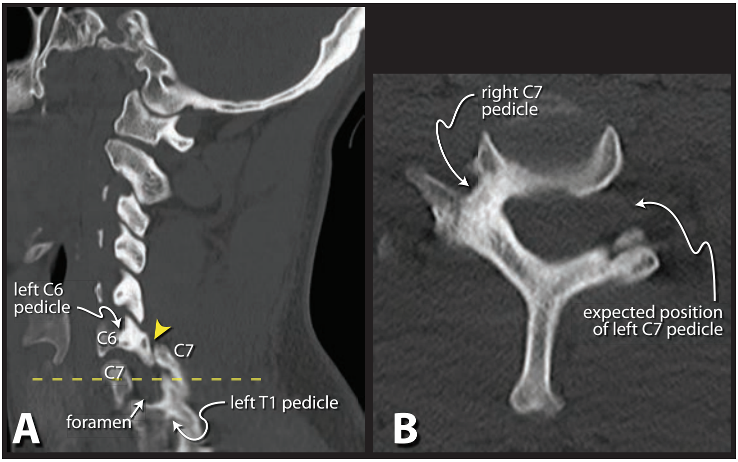

Fig. 71.6 Congenital absence of the left C7 pedicle.
The C6 inferior facet is positioned anterior to the superior C7 facet (*yellow arrowhead*) which mimics a unilateral locked left C6-7 facet. Note the neural foramen appears enlarged due to the absent pedicle (*short straight white arrow*).
Images: CT scan. A: Sagittal cut through the left facet joints. B: Axial CT cut at the level of the yellow broken line in A.

1. ipsilateral neural foramen appears enlarged. NB: this may falsely suggest the presence of a foraminal tumor such as a schwannoma
2. ipsilateral dorsally displaced dysplastic articular pillar and lamina. NB: the dysplastic reversed facet may mimic a locked facet[26]
3. ipsilateral dysplastic transverse process

Other clues for distinguishing this from ULF: there is no anterolisthesis in the lateral projection, and no deviation of the spinous processes from rotatory subluxation on the AP view.[27]

Most cases are asymptomatic. Symptoms that have been attributed to this include paresthesias or pain in the head, neck, shoulder, or arm. Surgery is unlikely to improve any symptoms.[27] It has been opined that the involved level may be less stable than normal, but no related serious spinal cord injuries have been reported.[27]

Treatment

Treatment options

Also see Practice guideline: Initial closed reduction in fracture-dislocation cervical SCI (p. 1147).

Unilateral locked facets: options include:

1. no treatment (i.e. leaving the facets locked): should generally be considered only for asymptomatic patients. May not be stable, and close follow-up is indicated with fusion recommended for failure
2. closed reduction with or without post-reduction fusion. May not be stable, and close follow-up is indicated with fusion recommended for failure
3. surgical intervention
   a) anterior approach: anterior cervical discectomy and fusion (ACDF) is the usual method. Cervical disc arthroplasty may be considered but is likely not as stable
   b) posterior approach: often open reduction and internal fixation
   c) combined anterior and posterior approach (360° fusion)

Nonoperative treatment for unilateral locked facets appears to have a higher rate of treatment failure, persistent pain, and neurologic deterioration than surgical treatment.[21]

Closed reduction of locked facets

✖ Contraindicated if traumatic disc herniation is demonstrated on MRI. Patients who cannot be assessed neurologically may be done using SSEP/MEP monitoring. Closed reduction was successful in 22% of 24 cases of ULF.[29] Two methods of closed reduction: traction or manipulation.

1. **traction**: more commonly employed in the U.S.
   a) initial weight (in lbs) ≈ 3 × cervical vertebral level, increase in 5–10 lb increments usually at 10–15 minute intervals until desired alignment is attained (assess neurologic exam (or SSEP/MEP) and lateral C-spine X-ray or fluoroscopy after each ≈ to avoid overdistraction)
   b) end points (i.e. do not add any more traction weight):
      - do not exceed 10 lbs per vertebral level (some say 5 lbs/level) under most circumstances. This is a guideline—you are trying to avoid overdistraction at the index level and at normal levels
      - distraction of perched/locked facet or desired reduction is achieved
      - if occipitocervical instability develops
      - if any disc space height exceeds 10 mm (overdistraction)
      - if any neurologic deterioration or deterioration of SSEP/MEP
   c) with unilateral locked facets, one may add gentle manual torsion *towards* the side of the locked facets. With bilateral locked facets, one may add gentle manual posterior tension (e.g. with a rolled towel under the occiput)
   d) once the facets are perched or distracted, gradual reduction of the weights will usually result in reduction—verify with X-ray (placing the neck in slight extension, e.g. with small shoulder roll, may help maintain the reduction)
2. **manipulation** (usually under anesthesia): less commonly employed,[22] more frequently used in Europe. Involves manually applying axial traction and sagittal angulation sometimes with rotation and direct pressure at the fracture level under fluoroscopy

Paraspinal muscle relaxation (but not enough to cause obtundation) may assist in reduction. Use IV diazepam (Valium®) and/or narcotic. General anesthesia may be used in difficult cases (with SSEP/MEP monitoring).

Once reduction is achieved, the patient is left in 5–10 lbs of traction for stabilization.

Disadvantage of closed reduction

1. fails to reduce ≈ 25% of cases of BLF
2. risks overdistraction at higher levels or worsening of other fractures
3. neurologic worsening following closed reduction may occur with traumatic disc herniation[23,30] and should be evaluated immediately with MRI and if confirmed treated with prompt discectomy
4. adds time and potentially pain to the patient's care, especially since many will go on to have surgical fusion anyway

Following closed reduction, the need for internal (operative) stabilization vs. external stabilization (i.e., bracing) may be addressed (see below).

Open reduction and fixation is usually required if reduction is not achieved. Closed reduction is often more difficult with bilateral locked facets than with unilateral.

Open reduction of locked facets

1. **posterior approach:** the most common approach. Although rare, this still subjects the patient to risk of deterioration from traumatically herniated disc. Therefore a pre-op MRI should be done if possible. Often requires drilling of the tip of the superior aspect of the articular facet of the level below. A foraminotomy is recommended when there are root symptoms to visualize and decompress the root
2. **anterior approach:** this is used when there is a traumatic disc herniation at the level of the subluxation. By removing the disc at the subluxed level and exploring the anterior epidural space, the risk of worsening deficit due to a traumatic herniated disc is theoretically reduced. A unilateral locked facet may be reduced by placing Caspar pins in the VB and then under traction rotating the pin in the body above the dislocation towards the side of the locked facet. Reducing bilateral locked facets is more difficult from an anterior approach
3. **combined anterior/posterior (360°)** approach: using anterior plate and posterior lateral mass screws/rods may eliminate the need for post-op external immobilization

Stabilization

Surgical fusion is commonly performed after successful closed reduction, failed closed reduction, or following open reduction.

If there are fracture fragments about the articular surfaces, there may be satisfactory healing with halo vest immobilization (for 3 months) once closed reduction is achieved.[31] Frequent X-rays are needed to rule out redislocation.[32] Flexion-extension X-rays are obtained upon halo removal and surgery is required for continued instability. Up to 77% of patients with unilateral or bilateral facet dislocation (with or without facet fracture fragments) will have a poor anatomic result with halo vest alone (although late instability was uncommon), suggesting that surgery should be considered for all of these patients.[33] Surgical fusion is more clearly indicated in cases without facet fracture fragments (ligamentous instability alone may not heal) or if open reduction is required.

If surgery is indicated, an MRI should be done beforehand if possible. A posterior approach is preferred if there are no anterior masses (such as traumatic disc herniation or large osteophytic spurs), if subluxation of the bodies is > one–third the VB width (suggesting severe posterior ligamentous injury), or for fractures of the posterior elements. A posterior approach is mandatory if there is an unreducible dislocation. See also Options for posterior approach (p. 1195).

71.6 Extension injuries of the subaxial cervical spine

71.6.1 Extension injury without bony injury

Extension injuries can produce spinal cord injury (SCI) without evidence of bony injury. Injury patterns include central cord syndrome (p. 1132) usually in an older adult with cervical spondylosis, and SCIWORA (see below) usually in young children. Middle-aged adults with hyperextension dislocations that reduce spontaneously immediately may present with SCI and no bony abnormality on X-ray, but there may be rupture of the anterior longitudinal ligament (ALL) and/or intervertebral disc on MRI or autopsy. Extension forces may also be associated with carotid artery dissections (p. 1578).

71.6.2 Minor extension injuries

Results from extension acting alone. Includes spinous process and lamina fractures. By themselves, are stable.

71.6.3 Extension compression injury

This is the most common mechanism of lateral mass/facet fractures (see below).

71.6.4 Lateral mass and facet fractures of the cervical spine

General information

Often results from extension combined with compression.

For C3 through C6, there is risk of vertebral artery injury.

Classification of cervical lateral mass and facet fractures

4 patterns identified in lateral mass and facet fractures[34] are shown in ▶ Table 71.5.

Anterior subluxation of the fractured vertebra was observed in 77% of whole lateral-mass fractures.[34]

Horizontal facet or separation fracture of the articular mass

Extension combined with compression and rotation may produce fracture of one pedicle and ipsilateral lamina which permits the detached articular mass ("floating" lateral mass) to rotate forward to a more horizontal orientation[35] (horizontalization of the facet) (▶ Table 71.5). May be associated with rupture of the anterior longitudinal ligament (ALL) and fissure of the disc at one or two levels. Neuro deficit is common. Unstable.

Table 71.5 Classification of cervical lateral mass & facet fractures[34]

Designation	Diagram	Description
separation fracture		fractures through lamina and ipsilateral pedicle. Permits *horizontalization* of facet[35] (see text)
comminuted fracture		multiple fractures. Often associated with lateral angulation deformity
split fracture		coronally oriented vertical fracture in 1 lateral mass, with invagination of the superior articular facet of the level below
traumatic spondylolysis		*bilateral* horizontal fractures through pars interarticularis, separating anterior spinal elements from posterior

Failure of nonoperative treatment

A study of *CT scans* of 26 ***unilateral*** cervical facet fractures[36] identified the risk factors shown below for failure of nonoperative treatment (▶ Fig. 71.7 for illustration of the measurement definitions): where the fracture fragment (FF) height was defined as the maximum tip-to-tip cephalocaudal height on sequential sagittal reconstructions.

Nonoperative management is likely to fail if FF is:

1. > 1 cm, or
2. > 40% of LM (the height of the intact contralateral lateral mass at the same level, defined as the maximum tip-to-tip cephalocaudal height on the sagittal reconstructions)

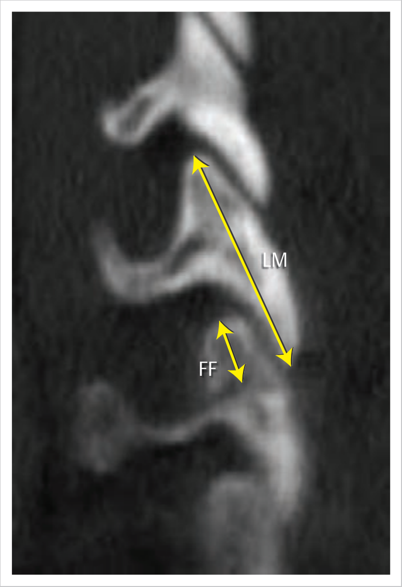

Fig. 71.7 Facet fracture fragment measurements. Sagittal CT through the facet joints. FF = fracture fragment height, LM = lateral mass height (measured on the *contralateral* side at the same level as the fracture, not as shown here which just illustrates the technique used to measure LM at a different level on the *same* side).

Surgical treatment of cervical lateral mass and facet fractures

Most cases can be treated with a posterior approach using fixation screws (lateral mass screws or pedicle screws[34]) and rods extending at least 1 level above and below the level of fracture (usually omitting a screw on the side of the fracture at the index level). Simultaneous neural decompression is performed when needed. Additional treatment with an anterior approach may be required for release of rigid deformity or for additional anterior column support.[34] Some separation fractures may be candidates for osteosynthesis (to preserve motion) using a cervical pedicle screw[34] that traverses the fracture.

An anterior approach is an alternative. Advantage: usually only 1 level needs to be fused. Disadvantages: decompression of compressing fragments cannot always be accomplished and requires disrupting an area that may not be compromised (if there is subluxation, the anterior column is probably compromised).

71.7 Treatment of subaxial cervical spine fractures

71.7.1 General information

Practice guideline: Treatment of subaxial cervical spine fractures or dislocations

Level III[37]

- closed or open reduction of subaxial fractures or dislocations with the goal of decompression of the spinal cord and restoration of the spinal canal
- stable immobilization either by internal fixation or by external immobilization to facilitate early patient mobilization and rehabilitation. If surgical treatment is employed, either anterior or posterior fixation is acceptable when a particular approach for decompression of the spinal cord is not required
- treatment with prolonged bed rest in traction if more contemporary treatment options are not available
- for patients with ankylosing spondylitis:
  - routine use of CT and MRI is recommended even after minor trauma
  - when surgical stabilization is required, posterior long segment instrumentation and fusion or a combined anterior/posterior procedure (360° fusion). Anterior stand-alone instrumentation and fusion procedures are associated with a failure rate of up to 50% in these patients

71.7.2 Management overview

Management of some specific types of C-spine fractures is covered in the corresponding preceding sections. For injuries not specifically addressed, general management principles are as follows[6]:

1. immobilize and reduce externally (if possible): may use traction × 0–7 days
2. determine if there is an indication for decompression as soon as practical (clinical conditions permitting), and decompress if needed. Although controversial, the following are generally accepted indications for *acute* decompression in patients without complete spinal cord injury:
   a) radiographic evidence of bone or foreign material in the spinal canal with associated spinal cord symptoms
   b) complete block on CT, myelogram, or MRI
   c) clinical judgment: e.g., a progressive incomplete spinal cord injury where the surgeon believes that decompression would be beneficial
3. ascertain stability of the injury (see ▶ Table 71.4)
   a) stable fractures: treat in non-halo orthosis for 1–6 weeks (p. 1124)
   b) unstable fractures: all of the following choices are appropriate, with little evidence (based on long-term spinal stability) to recommend one scheme over another in most cases
      - traction × 7 weeks, followed by orthosis × 8 weeks
      - halo × 11 weeks, followed by orthosis × 4 weeks
      - surgical fusion, followed by orthosis × 15 weeks
      - surgical fusion with internal immobilization (lateral mass screws & rods…) ± orthosis for short period of time (≈ several weeks)

71.7.3 Surgical treatment

In patients with complete spinal cord lesions

Operating on a patient with a complete cord injury (ASIA A and not in spinal shock) does not result in significant recovery of neurologic function.[38] If there is ongoing spinal cord compression and the bulbocavernosus reflex is absent, the patient may be in spinal shock. In this case, operate at the earliest time that is safe to do so at your institution. However, aggressive non-surgical reduction of traumatic subluxation should be pursued.

The primary goal of surgery in this setting is spinal stabilization, allowing the patient to be placed in a sitting position for improved pulmonary function, for psychological benefit, and to allow initiation of rehabilitation. Although the spine will fuse spontaneously in many cases (taking ≈ 8–12 weeks), surgical *stabilization* expedites the mobilization process and reduces the risk of delayed kyphotic angulation deformity. Early surgery may lead to further neurological injury, and should be delayed until the patient has stabilized medically and neurologically. In most cases, performing surgery within 4–5 days (if the patient is otherwise stable) is probably early enough to help reduce pulmonary complications.

In patients with incomplete lesions

Patients with incomplete cord injuries who have compromise of the spinal canal (by bone, disc, unreducible subluxation, or hematoma) and either do not improve with nonoperative therapy or deteriorate neurologically should undergo surgical decompression and stabilization.[38] This may facilitate some further return of spinal cord function. An exception may be the central cord syndrome (p. 1132).

Anterior or posterior?

The choice of technique depends to a large degree on the *mechanism* of injury, as the treatment should tend to counteract the instability, and ideally should not compromise structures that are still functioning. Instrumentation (wires/cables, lateral mass screws & rods, clamps…) immobilizes the area of instability while bony fusion is occurring. In the absence of bony fusion, all mechanical devices will eventually fail, and so it becomes a "race" between fusion and instrument failure. Extensive injuries (including teardrop fractures (p. 1184) and compression burst fractures) may require a combined anterior and posterior approach (staged, or in a single sitting; anterior decompression precedes posterior fusion).

Posterior immobilization and fusion

Indications: The procedure of choice for most *flexion* injuries. Useful when there is minimal injury to the vertebral bodies and in the absence of anterior compression of the spinal cord and nerves. Including: posterior ligamentous instability, traumatic subluxation, unilateral or bilateral locked facets, simple wedge compression fractures.

The most common technique consists of open or closed reduction, followed by lateral mass screws & rods (p. 1164). Interlaminar Halifax clamps are an alternative.[39] Although successes have been reported using methylmethacrylate,[40] it does not bond to bone and weakens with age, and thus its use in the setting of traumatic injury is *discouraged*.[41]

Choice of posterior technique: If the anterior weight-bearing column is significantly damaged, or if there is absence or compromise of the lamina or spinous processes, then either a combined anterior-posterior approach is needed or posterior rigid instrumentation (e.g., lateral mass screw-plate or rod fixation) with fusion is recommended.[42]

Anterior approach

Does not depend on integrity of posterior elements to achieve stability.

Indications:

1. fractured vertebral body with bone retropulsed into spinal canal (burst fracture)
2. most *extension* injuries
3. severe fractures of posterior elements that preclude posterior stabilization and fusion
4. may be used for traumatic subluxation of the cervical spine

Usually consists of:

1. corpectomy: decompresses the neural elements (if necessary) and removes fractured and structurally compromised bone
    a) decompression usually requires wide corpectomy, at least ≈ 16 mm (palpate anterior surface of vertebral body to determine width; note position of vertebral arteries on pre-op CT). NB: it is suggested to take the corpectomy no wider than 3 mm lateral to the medial edge of the longus colli muscle; this leaves ≈ 5 mm margin of safety to the foramen transversarium[43]
    b) if decompression is not needed, ≈ 12 mm corpectomy suffices (i.e., about the width of a half-inch cottonoid)
2. AND
    a) strut graft fusion: replaces the involved body or bodies with either:
        - bone (usually iliac crest, rib or fibula, either homologous or cadaveric)
        - or synthetic cage (e.g., titanium or PEEK)
    b) usually accompanied with compression plates
    c) usually followed with external immobilization
    d) corpectomy of > 1 level, or presence of injury to posterior elements is usually an indication for augmentation with posterior instrumentation

Complications of surgical treatment

1. hardware problems
   a) anterior cage problems
      - cage displacement/extrusion
      - cage subsidence/telescoping into endplate
      - vertebral body fracture
   b) problems with plating
      - screw pull-out, loosening, or breakage
      - fatigue fracture of plate
      - screw injury: nerve root, spinal cord, or vertebral artery
2. inadequate postoperative immobilization
   a) improper brace selected
   b) poor patient compliance with immobilization device
3. failure of graft to take (nonunion)
4. judgmental error
   a) failure to incorporate all unstable levels
   b) improper surgical approach

71.8 Spinal cord injury without radiographic abnormality (SCIWORA)

71.8.1 General information

Although spinal cord injuries are uncommon in children, there is a subgroup of these in which it is not possible to detect any bony or ligamentous abnormality on X-rays (including dynamic flexion-extension X-rays), CT scans, or myelograms. This was dubbed SCIWORA (an acronym for “Spinal Cord Injury Without Radiographic Abnormality”).[44] However, with the increased use of MRI, a number of soft tissue findings and spinal cord abnormalities have been identified, some of which have prognostic signficance (see below).[45] A more appropriate name might now be Traumatic Spinal Myelopathy with Exclusively MRI Findings (“T-SMEMF”) to denote that studies involving X-rays are negative by definition.

The age range of children with SCIWORA is 1.5–16 years; it has a much higher incidence in age ≤ 9 yrs.[46] This predilection for younger patients is attributed to the normally increased elasticity of their spinous ligaments and paravertebral soft-tissues.[44] The hypothesis is that the physiologic hypermobility of the young spine allows deformation to a degree that is beyond the tolerance of the spinal cord without causing fracture or discoligamentous instability. In addition to translational excursions, vertical stretching is also a possible mechanism of injury.[47] Other mechanisms include splitting of the growth zone of the vertebral body endplate and tearing of the anterior longitudinal ligament (ALL).[45]

There may be an increased risk of SCIWORA among young children with asymptomatic Chiari I malformation.[48]

Incidence: not accurately known, but probably 30-40% of children < 18 years of age with traumatic myelopathy have SCIWORA.[45]

71.8.2 Presentation of SCIWORA

54% of children with SCIWORA had a delay between injury (at which time some children experience transient numbness, paresthesias, Lhermitte’s sign (p. 1712), or a feeling of total body weakness) and the onset of *objective* sensorimotor dysfunction (“latent period”) ranging from 30 minutes to 4 days.

Four spinal cord injury patterns have been associated with SCIWORA[45]:

1. central cord syndrome (p. 1132)
2. Brown-Séquard syndrome (p. 1135)
3. partial cord syndrome: incomplete cord syndrome not consistent with either of the above
4. complete cord transection

Younger children tend to have upper cervical SCI, whereas older children skew towards the lower C-spine.

13% of SCIWORA cases involve the thoracic spine, almost exclusively from vehicular trauma.[45]

71.8.3 Radiographic evaluation

Practice guideline: Diagnosis of SCIWORA

Level III[49]
- MRI of the region of suspected injury
- radiographic screening of entire spine
- assess spinal stability with flexion-extension X-rays in the acute setting and at a late follow-up, even if MRI is negative for extraneural injury

✖ *not* recommended: spinal angiography or myelography

In addition to plain films and flexion-extension films (to identify overt instability which would require surgical fusion and would technically not be SCIWORA), should include MRI.

Possible MRI findings[45]:

1. extraneural findings. Fat-suppression sequences can enhance visualization of some findings. Includes: ALL rupture, loss of continuity of prevertebral soft-tissue low-signa stripe, splitting of the growth zone of the vertebral endplate, rupture of the PLL, intradiscal hemorrhages, hemorrhage in tectorial membrane, increased signal in the interspinous and interlaminar ligaments
2. neural findings: 5 patterns
   a) complete spinal cord disruption
   b) major cord hemorrhage: involves > 50% of cord cross-section. Severe deficit, poor prognosis for neurologic function
   c) minor cord hemorrhage: < 50% of cord cross-sectional involvement. Moderately severe deficit, fairly good prognosis for subtotal recovery
   d) edema only: T1 iso-intense or slightly hypo-intense, and T2 bright. Good prognosis
   e) no intraparenchymal abnormality: 35% of SCIWORA. Excellent chance of full recovery

There were no intraspinal space-occupying lesions in 13 patients studied with myelography/CT.[44]

71.8.4 Management

Practice guideline: Management of SCIWORA

Level III[49]
- external immobilization of the injured spinal segment for up to 12 weeks
- early discontinuation of external immobilization for patients who become asymptomatic and are confirmed to have no instability on flexion-extension X-rays
- avoidance of “high-risk” activities for up to 6 months after SCIWORA

Surgical intervention, including laminectomy, has shown no benefit in the few cases where it has been tried.[51]

Due to a 20% rate of repeat injury (some due to trivial trauma, and some without identifiable trauma) within 10 weeks of the original trauma when treated with only a rigid collar and restriction of contact sports (both for 2 months), more aggressive measures were initially recommended (▶ Table 71.6).

Table 71.6 Treatment protocol for SCIWORA (modified[50])

- admit patient to hospital (helps emphasize seriousness of injury)
- BR with rigid cervical collar until flexion-extension films are normal
- MRI of cervical spine to document presence of spinal cord injury
- detailed discussion with patient and family about seriousness of injury and rationale for treatment outlined here
- immobilization in Guilford brace for 3 months[a]
- prohibition of contact and noncontact sports
- regular follow-up visits for monitoring condition and compliance
- liberalize activities at 3 months if flexion-extension films are normal

[a] this represents an extremely conservative recommendation, a less restrictive recommendation is immobilization for 1–3 weeks[51]; see **Practice guideline: SCIWORA** (p. 1197).

72 Thoracic, Lumbar, and Sacral Spine Fractures

72.1 Assessment and management of thoracolumbar fractures

72.1.1 General information

A widely used model for thoracolumbar spine stability is the 3-column model of Denis (see below). See also the more recent TLICS system (p. 1206). Note: these systems are for *trauma*, see the Spine Instability Neoplastic Score (SINS) (▶ Table 55.12) for stability assessment in metastatic spine disease.

72.1.2 Three-column model

General information

Denis' 3-column model of the spine (▶ Fig. 72.1) attempts to identify *CT* criteria of instability of *thoracolumbar* spine fractures.[1] This model has generally good predictive value; however, any attempt to create "rules" of instability will have some inherent inaccuracy.

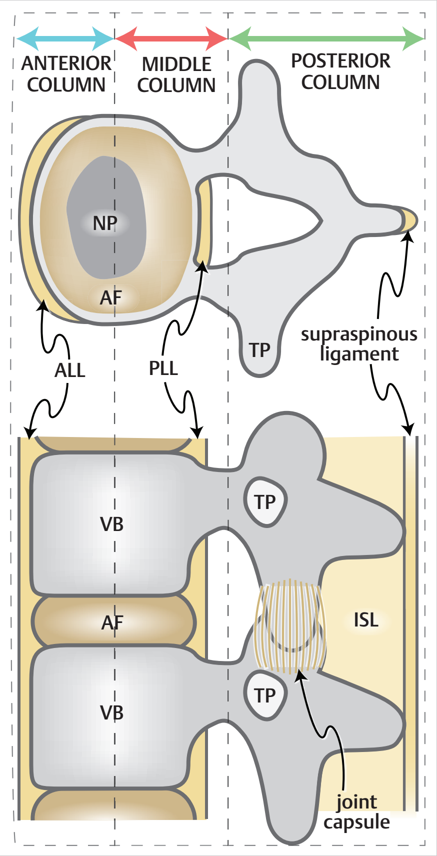

Fig. 72.1 Three-column model of the spine (Denis).
Image: top: viewed from above, bottom: viewed from the side.
Abbreviations: ALL = anterior longitudinal ligament; AF = anulus fibrosus; ISL = interspinous ligament; NP = nucleus pulposus; PLL = posterior longitudinal ligament; TP = transverse process; VB = vertebral body. (Adapted from Spine, Denis F, Vol. 8, pp. 317–31, 1983, with permission.)

Definitions

- **anterior column**: anterior half of disc and vertebral body (VB) (includes anterior anulus fibrosus (AF)) plus the anterior longitudinal ligament (ALL)
- **middle column**: posterior half of disc and vertebral body (includes posterior wall of vertebral body and posterior AF), and the posterior longitudinal ligament (PLL)
- **posterior column**: posterior bony complex (posterior arch) with interposed posterior ligamentous complex (supraspinous and interspinous ligament, facet joints and capsule, and ligamentum flavum (LF)). Injury to this column alone does *not* cause instability in flexion

Classification into major and minor injuries

Minor injuries

Involve only a part of a column and do not lead to acute instability (when not accompanied by major injuries). Includes:

1. fracture of transverse process: usually neurologically intact except in two areas:
   a) L4–5 → lumbosacral plexus injuries (there may be associated renal injuries, check U/A for blood)
   b) T1–2 → brachial plexus injuries
2. fracture of articular process or pars interarticularis
3. isolated fractures of the spinous process: in the TL spine: these are usually due to direct trauma. Often difficult to detect on plain X-ray
4. isolated laminar fracture: rare. Should be stable

Major injuries

The McAfee classification describes 6 main types of fractures.[2] A simplified system with four categories follows (also see ▶ Table 72.1):

Table 72.1 Column failure in the four major types of thoracolumbar spine injuries

Fracture type	Column		
	Anterior	Middle	Posterior
compression	compression	intact	intact, or distraction if severe
burst	compression	compression	intact
seat belt	intact or mild compression of 10–20% of anterior VB	distraction	
fracture-dislocation	compression, rotation, shear	distraction, rotation, shear	

Source: Adapted[1] with permission.

▶ **Type 1: Compression fracture.** Compression failure of anterior column only (▶ Fig. 72.2). Middle column *intact* (unlike the 3 other major injuries below) acting as a fulcrum

1. 2 subtypes:
   a) anterior: most common between T6–8 and T12–3
      - lateral X-ray: wedging of the VB anteriorly, no loss of height of posterior VB, no subluxation
      - CT: spinal canal intact. Disruption of anterior endplate
   b) lateral (rare)
2. clinical: no neurologic deficit

▶ **Type 2: Burst fracture.** See ▶ Fig. 72.3. Pure axial load → compression of vertebral body → compression failure of anterior and middle columns. Occur mainly at TL junction, usually between T10 and L2

1. 5 subtypes; L5 burst fractures (p. 1206) may constitute a rare subtype
   a) fracture of both endplates: seen in lower lumbar region (where axial load → increased extension, unlike T-spine where axial load → flexion)
   b) fracture of superior endplate: the most common burst fracture. Seen at TL junction. Mechanism = axial load + flexion
   c) fracture of inferior endplate: rare
   d) burst rotation: usually midlumbar. Mechanism = axial load + rotation
   e) burst lateral flexion: mechanism = axial load + lateral flexion

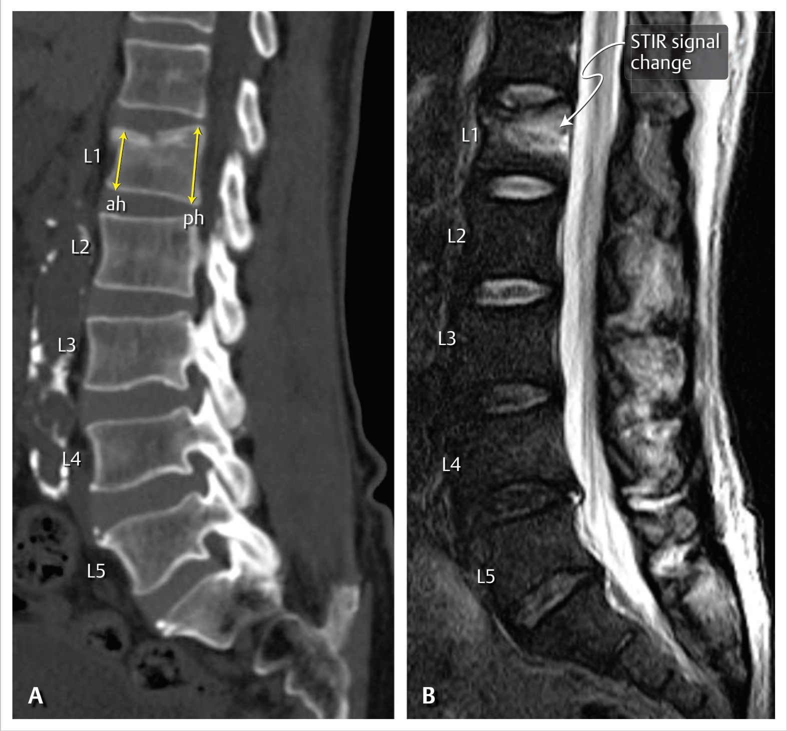

Fig. 72.2 L1 compression fracture.
Mild loss of anterior height with no involvement of middle or posterior columns.
STIR signal changes indicate the fracture is recent.
Yellow double arrows: “ah” = anterior height of the fractured vertebral body, “ph” = posterior height.
A: Sagittal (off midline) bone-window CT, B: Sagittal STIR MRI.

2. radiographic evaluation
    a) lateral X-ray: cortical fracture of posterior VB wall, loss of posterior VB height, retropulsion of bone fragment from endplate(s) into canal
    b) AP X-ray: increase of interpediculate distance (IPD), vertical fracture of lamina, splaying of facet joints: ↑ IPD indicates failure of *middle* column
    c) CT: demonstrates break in posterior wall of VB with retropulsed bone in spinal canal (average: 50% obstruction of canal area), increase in IPD with splaying of posterior arch (including facets)
    d) MRI: compromise of anterior canal by bone fragment; possible cord compression usually with fragments occupying > 50% of the canal diameter
    e) MRI or myelogram: compression in spinal canal
3. clinical: depends on level (thoracic cord more sensitive and less room in canal than conus region), the impact at the time of disruption, and the extent of canal obstruction
    a) ≈ 50% intact at initial examination (half of these recalled leg numbness, tingling, and/or weakness initially after trauma that subsided)
    b) of patients with deficits, only 5% had *complete* paraplegia

► **Type 3: Seat belt fracture.** Flexion across a fulcrum anterior to the anterior column (e.g., lap type seat belt) → compression of anterior column & distraction failure of both middle and posterior columns. May be bony or ligamentous. Current terminology: flexion-distraction injury (FDI)

1. 4 subtypes
    a) **Chance fracture** (first desribed by George Quentin Chance[3]): horizontal fracture, classically one level, purely through bone, splitting the spinous process, laminae, pedicles, and VB (► Fig. 72.4)

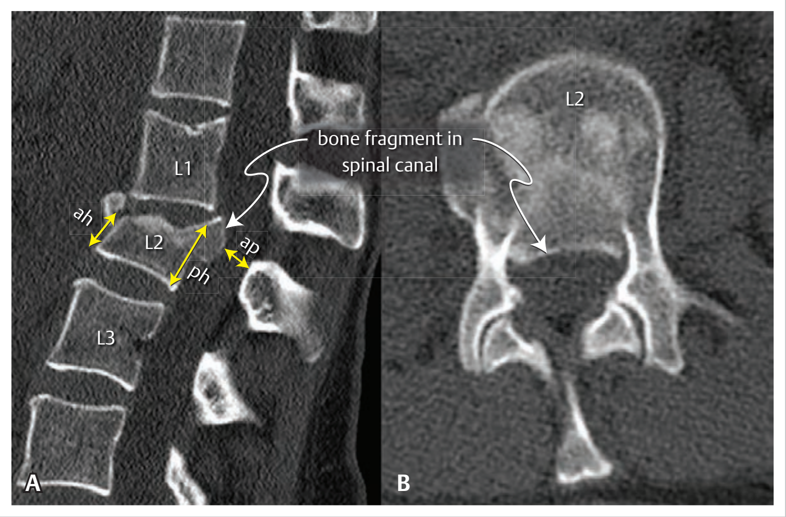

Fig. 72.3 L2 burst fracture.
Note the intact posterior elements (by definition in a burst fracture).
Yellow double arrows: “ap” = residual AP diameter of the canal, “ah” = anterior height of the fractured vertebral body, “ph” = posterior height.
CT scan, bone windows. A: Sagittal, B: Axial.

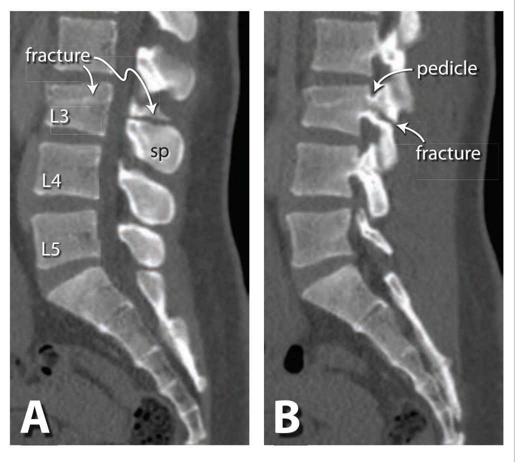

Fig. 72.4 L3 Chance fracture (Denis Type 3a).
Image: CT scan, bone windows. A: Sagittal midline, note the compression fracture through the vertebral body and the distraction fracture through the spinous process (sp); B: Parasagittal through right pedicle, showing the fracture extends through the pedicle.

  b) one level, through ligaments
  c) two level, through bone in middle column, through ligament in anterior and posterior columns
  d) two level, through ligament in all 3 columns
2. radiographic evaluation
  a) plain X-ray: ↑ interspinous distance, pars interarticularis fractures, and horizontal split of pedicles and transverse process. No subluxation

   b) CT: axial cuts are poor for this type (most of fracture is in plane of axial CT cuts). Sagittal and coronal reconstructions demonstrate well. May disclose a pars fracture
   c) MRI: T2 to check for canal compromise, STIR to check for ligamentous injury
3. clinical: no neurologic deficit

▸ **Type 4: Fracture-dislocation.** Failure of all 3 columns due to compression, tension, rotation or shear → subluxation or dislocation

1. radiographic evaluation
   a) X-ray: occasionally, may be reduced when imaged. Look for other markers of significant trauma (multiple rib fractures, unilateral articular process fractures, spinous process fractures, horizontal laminar fractures, or increased signal on MRI)
   b) CT scan: almost always indicated for assessment and surgical planning
   c) MRI: assesses nerve involvement. Increased STIR or T2 signal in ligaments and/or disc can provide information about possible injury to those structures
2. 3 subtypes
   a) flexion rotation: posterior and middle columns totally ruptured, anteriorly compressed → anterior wedging
      - lateral X-ray: subluxation or dislocation. Preserved posterior VB wall. Increased interspinous distance
      - CT: rotation and offset of VBs with ↓ canal diameter. Jumped facets
      - clinical: 25% neurologically intact. 50% of those with deficits were complete paraplegics
   b) shear: all 3 columns disrupted (including ALL)
      - when trauma force is directed posterior to anterior (more common) VB above shears forward fracturing the posterior arch (→ free floating lamina) and the superior facet of the inferior vertebra
      - clinical: all 7 cases were complete paraplegics
   c) flexion distraction subtype of fracture-dislocation
      - radiographically resemble seat belt type with addition of subluxation, or with compression of anterior column > 10–20% (▸ Fig. 72.5)
      - clinical: neurologic deficit (incomplete in 3 cases, complete in 1)

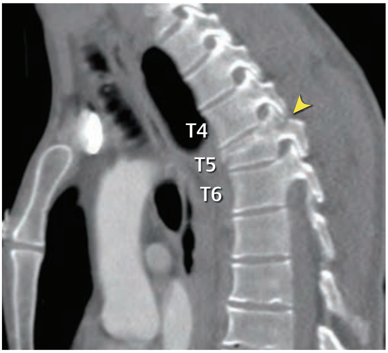

Fig. 72.5 Flexion distraction type of fracture dislocation (Denis Type 4c) of T5.
Image: CT scan, sagittal cut through the pedicles, bone windows.
Note the anterior compression fracture of > 10-20% through the vertebral body and the distraction fracture through the pedicle (*yellow arrowhead*).

Associated injuries

In addition to the above, associated injuries include: vertebral endplate avulsion, ligamentous injuries, and hip and pelvic fractures. Thoracolumbar fractures may be associated with hemodynamic instability as a result of hemothorax or aortic injury. Fractures of the transverse processes may be associated with abdominal trauma (e.g., renal injuries at L4–5).

Stability and treatment of thoracolumbar spine fractures

Minor injuries

Isolated thoracolumbar transverse process fractures (as demonstrated on spinal CT) do not require intervention or consultation of a spine service.[4,5]

Major spine injuries

Denis categorized the instability as:

- 1st degree: mechanical instability
- 2nd degree: neurological instability
- 3rd degree: both mechanical & neurological instability

Anterior column injury

Isolated anterior column injuries are usually stable and are treated as outlined in ▶ Table 72.2.

The following exceptions may be *unstable* (1st degree) and often require surgery[1,6]:

Table 72.2 Treatment of stable anterior or middle column thoracolumbar spine injuries

- treat initially with analgesics and recumbency (bed-rest) for comfort
- diminution of pain is a good indication to commence mobilization with or without external bracing (corset or Boston brace or extension TLSO × ≈ 12 weeks) depending on the degree of kyphosis
- vertebroplasty (± kyphoplasty) may be an option (p. 1212)
- serial X-rays to rule out progressive deformity

Unstable compression fractures

1. a single compression fracture with:
   a) loss of > 50% of height with angulation (particularly if the anterior part of the wedge comes to a point)
   b) excessive kyphotic angulation at one segment (various criteria are used, none are absolute. Values quoted: > 30°, > 40°)
2. 3 or more contiguous compression fractures
3. neurologic deficit (generally does not occur with pure compression fracture)
4. disrupted posterior column or more than minimal middle column failure
5. progressive kyphosis: risk of progressive kyphosis is increased when loss of height of anterior vertebral body is > 75%. Risk is higher for lumbar compression fractures than thoracic

Middle column failure

These are unstable (often requiring surgery) with the following exceptions, which should be stable (stable injuries may be treated as outlined in ▶ Table 72.2).

▶ Stable middle column fractures

- above T8 if the ribs and sternum are intact (provides anterior stabilization)
- below L4 if the posterior elements are intact
- Chance fracture (anterior column compression, middle column distraction) (▶ Fig. 72.4)
- anterior column disruption with minimal middle column failure

Posterior column disruption

Not *acutely* unstable unless accompanied by failure of the middle column (posterior longitudinal ligament and posterior anulus fibrosus). However, *chronic* instability with kyphotic deformity may develop (especially in children).

Seat belt type injuries without neurologic deficit

No immediate danger of neurologic injury. Treat most with external immobilization in extension (e.g., Jewett hyperextension brace or molded TLSO).

Fracture-dislocation

Unstable. Treatment options:

1. surgical decompression and stabilization: usually needed in cases with
   a) compression with > 50% loss of height with angulation
   b) or kyphotic angulation > 40° (or > 25%)
   c) or neurologic deficit
   d) or desire to shorten length of time of bedrest
2. prolonged bedrest: an option if none of the above are present

When vertebral body resection (vertebral corpectomy) is performed, options to access: transthoracic or transabdominal approach (or combined), transpedicular (for thoracic spine), lateral (retroperitoneal/retropleural) approach. Fracture and compression usually occurs at the superior margin of vertebral body, thus start resection at the *inferior* disc interspace. Followed by strut graft (cage or bone: iliac crest or fibula or tibia). Posterior instrumentation is usually required.

Burst fractures

Most thoracolumbar burst fractures occur at T12, L1 & L2.[7] Not all burst fractures are alike. Some burst fractures may eventually cause neurologic deficit (even if no deficit initially). Middle column fragments in canal endanger the neuro elements. Criteria have been proposed to differentiate mild burst fractures from severe ones. No system is uniformly accepted.

Surgical indications[1,8]: burst fracture with any of the following (see ▶ Fig. 72.3):

- anterior vertebral body height ≤ 50% of the posterior height
- residual canal diameter ≤ 50% of normal (note: retropulsed bone in the canal usually remodels over time to cause less compression, with either bracing or surgery and is therefore controversial as an isolated indication for surgery[9,10])
- kyphotic angulation ≥ 20°
- when the interpediculate distance (which is usually abnormally increased on the initial films) widens further on AP X-ray when standing in brace/cast
- neurologic deficit (incomplete)
- progressive kyphosis

Common surgical options for burst or severe compression fractures:

1. if instrumentation alone is needed
   a) can place pedicle screws in 2 levels above and 2 levels below the fracture
   b) if the index level (the fractured level) can be included (i.e., if the pedicles are intact enough to accept shorter screws), similar biomechanical stability can be achieved by placing screws at the index level and then just 1 above and 1 below[11]
2. if decompression of the spinal canal and/or anterior support is needed, corpectomy and strut graft (e.g., with expandable cage) with pedicle screws may be used. Approaches:
   a) from posterior approach e.g., laminectomy with transpedicular approach and impacting bone anteriorly out of canal with a mallet and reverse angled Scoville curette (here, open pedicle screws would be used), or
   b) lateral corpectomy and removal of bone from canal (here percutaneous pedicle screws may be used)

For those not undergoing surgery (i.e., when surgery is not required or is contraindicated), an option is to treat with recumbency from 1–6 weeks (the duration depending on pain and degree of deformity).[8] Avoid early ambulation → further axial loading (even in cast). When appropriate, begin ambulation in an orthosis (e.g., molded thoracolumbar sacral orthosis (TLSO) or a Jewett brace) and follow patient for 3–5 months with serial X-rays to detect progressive collapse or angulation which may need further intervention.

L5 burst fractures may be an exception to the usual management. They comprise only 2.2% of thoracolumbar fractures, and tend to be due to axial compression without rotation.[12] Disc herniation and delayed degeneration is common. Patients with neurologic deficit: surgery is recommended, impacting bone fragments anteriorly and removing herniated disc material, and fusing L4–S1 (with short L5 screws when possible). Vertebral body replacement from a posterior approach carries a risk of paralysis.[12]

72.1.3 Thoracolumbar injury classification and severity score (TLICS)

The TLICS system has been proposed to simplify classification and discussion of thoracolumbar fractures.[13,14] Points are assigned as shown in ▶ Table 72.3. The scores are summed, and management guidelines are given in ▶ Table 72.4.

Neurologic deficit, especially when partial, favors surgery. Note: this system is for trauma, see the Spine Instability Neoplastic Score (SINS) (▶ Table 55.12) for stability assessment in metastatic spine disease.

Table 72.3 Thoracolumbar injury classification & severity score (TLICS)[13,14]

Category	Finding	Points	Score
Radiographic findings	compression fx	1	**(1 - 4)**
	burst component or lateral angulation > 15°	2	
	translational/rotational injury	3	
	distraction injury	4	
Neurologic status	intact	0	**(0 | 2 | 3)**
	root injury	2	
	complete SCI (cord or conus medullaris)	2	
	incomplete SCI (cord or conus medullaris)	3	
	cauda equina syndrome	3	
Integrity of posterior ligamantous complex	intact	0	**(0 | 2 | 3)**
	undetermined	2	
	definite injury	3	
TLICS Score → TOTAL			**(1 - 10)**

Table 72.4 Management based on TLICS

TLICS	Management
≤ 3	nonoperative candidates
4	"gray zone" may be considered for operative or nonoperative management
≥ 5	surgical candidates

72.2 Surgical treatment

72.2.1 Ligamentotaxis

If the PLL is intact (may not be the case with middle column failure), distraction on the vertebral levels across the fractured level may be able to "pull" retropulsed fragments out of the canal and back towards their normal position (ligamentotaxis) although this is not assured.[15] Ligamentotaxis has a better chance of succeeding if performed within 48 hours of injury. From a posterior approach with laminectomy: intraoperative ultrasound may demonstrate residual canal fragments,[16] and if needed the fragments may be impacted anteriorly out of the canal, e.g., using tamps such as Sypert spinal impactors (Aesculap surgical instruments) or reverse cutting Scoville curettes. It is important not to overdistract to avoid neural injury.

72.2.2 Choice of surgical approach

The posterior approach is preferred when there is not a specific need to go from the front.

72.2.3 Burst fractures

Choice of approach

Surgical considerations: a posterior approach is preferred if there is a dural tear, whereas a burst fracture with partial deficit and canal compromise may be treated more effectively from an anterior approach.[2] A small progression in angular deformity may occur when posterior stabilization is performed alone (since the injury to the anterior column is not corrected), but by itself usually does not require intervention.

For a posterior approach

In an ideal situation (good bone quality, pedicle screw placement goes well (i.e., no fracture, no breach), and nonsmoking patient), one can fuse/rod one above and one below the fracture (using pedicle screws; longer constructs are needed with laminar hooks). With a short segment fusion like this, approximately 10° of lordosis will be lost with time; therefore, one should try to overcorrect a little to accommodate the anticipated settling. If the patient does not meet the above criteria (e.g., poor bone quality), an option is to “rod long, fuse short” (e.g., rod 2 levels above and below the fracture but fuse only 1 level above and below) and then to remove the hardware when the fusion is solid (e.g., at 8–12 months)—this avoids fusing a nonpathologic segment just to get a better anchor. Junctional deterioration to the point that further surgery is needed often occurs at 3 years when 4 segments are fused, as opposed to occurring at 8–9 years when only 3 levels are fused. Fusing across critical levels (i.e., thoracolumbar junction with T11 or L1 compression fractures) requires that the fusion incorporate 2–3 levels on each side of the junction (the forces of the long segment of the relatively immobile thoracic spine with the lumbar spine at the T-L junction increase the risk of nonunion).

For thoracic fractures that are not severe and do not require decompression, an option is to place pedicle screws and rods (which can be done percutaneously) without placing any graft. The concept is that the ribs anteriorly and the screws/rods posteriorly provide adequate stabilization while the fractured VB heals. The hardware can be removed electively once the fusion is solid (usually at 8–12 months). This is more commonly practiced in Europe than the U.S.

72.2.4 Wound infections

Postoperative wound infections with spinal instrumentation are usually due to *Staphylococcus aureus*. With titanium hardware, a reasonable initial attempt may be debridement of devitalized tissue (and any loose onlay bone graft) and thorough washout (typically with 3 L of antibiotic irrigation (e.g., 50,000 U of Bacitracin in 3 L of sterile irrigant) flushed into the wound using a pulsed lavage device—avoiding direct irrigation of any exposed dura) without removal of instrumentation, followed by antibiotics.[2] If this is inadequate, a repeat washout with a vascularized wound closure (e.g., with a reconstructive plastic surgeon) may succeed. If not, removal of instrumentation may occasionally be required.

72.3 Osteoporotic spine fractures

72.3.1 General information

Osteoporosis is defined as a condition of skeletal fragility as a result of low bone mass, microarchitectural deterioration of bone, or both[17] in the absence of a mineralization defect. It is found most commonly in postmenopausal white females, and is rare prior to menopause. Lifetime risk of symptomatic vertebral body (VB) osteoporotic compression fractures is 16% for women, and 5% for men. It affects 75 million people in the U.S., Europe, and Japan.[18] There are ≈ 700,000 VB compression fractures per year in the U.S.

These patients are often found to have significant VB compression fractures on plain films after presenting with back pain following a seemingly minor fall. CT often shows an impressive appearing amount of bone retropulsed into the canal.

72.3.2 Bone physiology

Bone is a dynamic tissue, constantly undergoing remodeling in a delicate balance between resorption by osteoclasts and new bone deposition by osteoblasts. Osteoporosis results from an imbalance in this process that favors resorption.

72.3.3 Risk factors

Factors that increase the risk of osteoporosis include:

1. weight < 58 kg
2. cigarette smoking[19]
3. low-trauma VB fracture in the patient or a first degree relative
4. drugs
    a) heavy alcohol consumption
    b) ASMs (especially phenytoin)
    c) warfarin
    d) chronic heparin use (p. 172)
    e) steroid use:
        - bone changes can be seen with 7.5 mg/d of prednisone for > 6 months
        - VB fractures occur in 30–50% of patients on prolonged glucocorticoids
5. postmenopausal female

6. males undergoing androgen deprivation therapy (e.g., for prostate Ca). Orchiectomy or ≥ 9 doses of gonadotropin-releasing hormone agonists had a 1.5 fold increase in risk of all fractures[20]
7. physical inactivity
8. low calcium intake
9. low serum levels of vitamin D (which decreases calcium absorption—see below). Lab: serum 25-hydroxyvitamin D [25(OH)D], AKA calcidiol is the best indicator of vitamin D status (▸ Table 72.6)
10. Cushing's disease for > 2 years duration

Factors that protect against osteoporosis include impact exercise and excess body fat.

72.3.4 Diagnostic considerations

To differentiate osteoporotic compression fractures from other pathologic fractures, see Pathologic fractures of the spine (p. 1679).

Pre-fracture diagnosis

1. measuring bone fragility directly is not possible
2. the best radiographic correlate with bone fragility is bone mineral density (BMD) determined using DEXA scan (see below)
3. patients with low-trauma fractures or fragility fractures are considered osteoporotic even if their BMD are greater than these cutoffs
4. measuring Hounsfield units on CT scans of lumbar VBs may be used (see below)
5. FRAX® tool (p. 1210)

▸ **CT scan.** Estimating BMD of lumbar VBs by CT may have advantages over DEXA scans:
- CT may reflect changes in BMD earlier than DEXA[21]
- CT can specifically assess S1 which DEXA does not[22]

Rule of thumb: Hounsfield units of a vertebral body < 100 correlates with significant risk of hardware failure.

▸ **DEXA scan (dual energy X-ray absorptiometry).** A DEXA scan (AKA DXA) is the preferred way to measure BMD which is expressed in g/cm^2.
1. proximal femur: BMD measurement in this location is the best predictor for future fractures
2. LS spine: DEXA typically measure BMD of L1–L4 individually and also calculates an aggregate. L1–4 is the most useful region to predict bone integrity for lumbar spinal fusions. Both AP *and* lateral views are needed since the AP often overestimates BMD because of superimposition of overlying posterior elements and aortic calcifications
3. forearm BMD may be used if hip or spine are unsuitable, but is not very accurate

Interpretation of DEXA scan results:
1. results are reported as
   a) T-score: norms for *healthy young adults* of the same gender
   b) Z-score: norms of subjects of *same age* and sex as the patient
2. the *lowest* T-score (of hip, lumbar spine or radius) is used for determination
3. diagnostic criteria: T-scores are not the same as standard deviations (SD) but they can be used that way.[23] With a normal distribution having a mean of 0, 68% of the population falls within 1 SD, 95% within 2 SD, and 99.7% within 3 SD.
   WHO classifications of BMD are shown in ▸ Table 72.5

Table 72.5 WHO classification of BMD based on DEXA T-score[23,24]

T-score	Description
T-score ≥ –1	normal
T-score < –1 and T-score > –2.5	osteopenia*
T-score ≤ –2.5	osteoporosis
T-score ≤ -2.5 *plus* fragility fracture	severe osteoporosis

* the International Society for Clinical Densitometry (ISCD) prefers the term "low mineral density"[23]

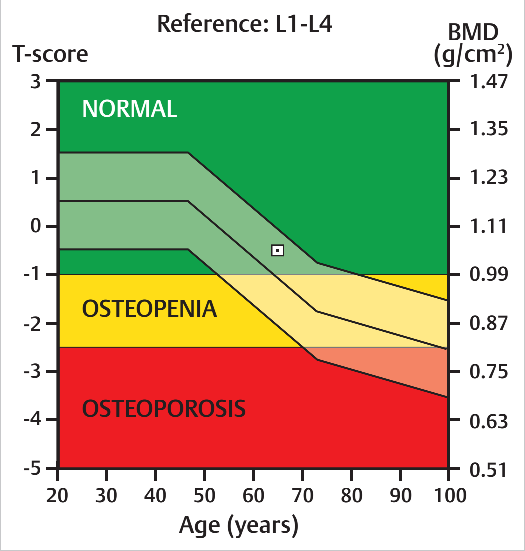

Fig. 72.6 Bone mineral density (BMD) graph. Example of a typical BMD graph generated from a DEXA scan.

Results are often depicted graphically as shown in ▶ Fig. 72.6.

▶ **FRAX® tool.** The FRAX® tool was developed for the WHO and uses femoral neck BMD (in g/cm^2) to calculate 10-year risk of hip fracture and also “major osteoporotic fracture” (fracture involving proximal femur, spine, proximal humerus, or distal radius).

Post-fracture considerations

1. other causes of pathologic fracture, especially neoplastic (e.g., multiple myeloma, metastatic breast cancer…) should be ruled out
2. younger patients with osteoporosis require evaluation for a remediable cause of osteoporosis (hyperthyroidism, steroid abuse, hyperparathyroidism, osteomalacia, Cushing’s syndrome…)

72.3.5 Prevention of osteoporosis

High calcium intake during childhood may increase peak bone mass.

In adulthood: increased calcium intake is ineffective. Weight-bearing exercise in adulthood helps slow calcium loss from bones. Also effective: estrogen (see below), bisphosphonates (alendronate and risedronate), and raloxifene.

72.3.6 Treatment of osteoporosis

See references.[25,26,27,28]

Drugs that increase bone formation include:

1. parathyroid hormone analogues (PTAs): lifetime treatment limit of 2 years because the effectiveness diminishes and the risk of osteosarcoma (in rats) increases. Unlike drugs that reduce resorption, PTAs used intermittently (e.g., once daily) stimulate osteoblasts preferentially over osteoclasts with the result of laying down of new bone. FDA approved for patients at high risk of fracture who: are postmenopausal women, are men with hypogonadal osteoporosis, or either gender with osteoporosis due to systemic glucocorticoids. PTAs have been used off-label to treat patients with osteopenia/osteoporosis prior to spine instrumentation. Prior to treatment: check serum levels of intact parathyroid hormone (iPTH) and 25(OH)D. Do not use until any vitamin D

deficiency is corrected. Monitor Ca++ during therapy (transient rise in Ca++ is common, but persistent hypercalcemia has been reported[29])

✖ Contraindication: patients with increased risk of osteosarcoma (e.g., Paget's disease, unexplained elevation of alkaline phosphatase), prior radiation therapy involving the skeleton, young patients with open epiphyses, patients with hypercalcemia, ± patients on digoxin (these agents may increase calcium levels)

a) teriparatide (Forteo®, Bonsity®):
   the bioactive 34 amino acid N-terminus segment of parathyroid hormone manufactured using recombinant DNA. Unknown if teriparatide reduces the risk of fractures in men
   Rx: 20 mcg SQ daily. Total lifetime limit of all parathyroid analogues: 2 years

b) abaloparatide (Tymlos™):
   a recombinant DNA copy of the entire human parathyroid hormone.
   Rx: 80 mcg SQ daily. Total lifetime limit of all parathyroid analogues: 2 years

2. sodium fluoride: 75 mg/d increases bone mass but did *not* significantly reduce the fracture rate. 25 mg PO BID of a delayed-release formulation (Slow Fluoride®) reduced fracture rate but may make bone more fragile and could increase risk of hip fractures. Fluoride increases demand for Ca^{++}, therefore supplement with 800 mg/d Ca^{++} and 400 IU/d vitamin D. Not recommended for use > 2 yrs

Drugs that reduce bone resorption are less effective on cancellous bone (found mainly in the spine and at the end of long bones[26]). Improvement in spine bone mineral density accounts for only a small part of the observed reduction in the risk of vertebral fracture.[30] Medications include:

1. estrogen: cannot be used in men. Estrogen hormone replacement therapy (HRT) increases vertebral bone mass by > 5% and decreases rate of vertebral fractures by 50%. Also relieves post-menopausal symptoms and reduces risk of CAD. However, use is limited since HRT increases the risk of breast cancer[31] and breast cancer recurrence[32] as well as DVT
2. calcium: current recommendation for postmenopausal women: 1,000–1,500 mg/d taken with meals[33]
3. vitamin D or analogues: promote calcium absorption from the GI tract. Typically administered with calcium therapy (either calcium or vitamin D alone are less effective). Vitamin D 400–800 IU/d is usually sufficient. If urinary Ca^{++} remains low, high-dose vitamin D (50,000 IU q 7–10 d) may be tried. Since high-dose formulations have been discontinued in the U.S., analogues such as calcifediol (Calderol®) 50 mcg/d or calcitriol (Rocaltrol®) up to 0.25 mcg/d may be tried with Ca^{++} supplement. Serum levels of 25-hydroxyvitamin D [25(OH)D], AKA calcidiol is the best indicator of vitamin D status. The significance of vitamin D levels are shown in ▶ Table 72.6.[34] With high-dose vitamin D or analogues, monitor serum and urinary Ca^{++}

Table 72.6 Serum 25-hydroxyvitamin D (25(OH)D) levels

ng/ml[a]	nmol/L[a]	Interpretation
< 10–11	< 25–27.5	vit D deficiency → rickets (in peds) and osteomalacia (adults)
< 10–15	< 25–37.5	inadequate for bone and overall health
≥ 15	≥ 37.5	adequate for bone and overall health
consistently > 200	consistently > 500	potentially toxic → hypercalcemia & hyperphosphatemia

[a]1 ng/ml = 2.5 nmol/L

4. calcitonin: a hormone synthesized by the thyroid gland which decreases bone resorption by osteoclasts. May be derived from a number of sources, salmon is one of the more common ones. The skeletal response is maximal during the first 18–24 months of therapy. Benefit in preventing fractures is less well-established[28]
   a) parenteral salmon calcitonin (Calcimar®, Miacalcin®): indicated for patients for whom estrogen is contraindicated. Expensive ($1,500–3,000/yr) and must be given IM or sub-Q. 30–60% of patients develop antibodies to the drug which negates its effect. ℞: 0.5 ml (100 U) of calcitonin (given with calcium supplements to prevent hyperparathyroidism) SQ q d
   b) intranasal forms (Miacalcin nasal spray): less potent (works better in older women > 5 yrs post menopause). 200–400 IU/d given in one nostril (alternate nostrils daily) plus Ca^{++} 500 mg/d and vitamin D
5. bisphosphonates: carbon-substituted analogues of pyrophosphate have a high affinity for bone and inhibit bone resorption by destroying osteoclasts. Not metabolized. Remain bound to bone for several weeks

   a) etidronate (Didronel®), a 1st generation drug. Not FDA approved for osteoporosis. May reduce rate of VB fractures, not confirmed on F/U. Possible increased risk of hip fractures due to inhibition of bone mineralization may not occur with 2nd & 3rd generation drugs listed below. ℞ 400 mg PO daily × 2 wks followed by 11–13 weeks of Ca^{++} supplementation
   b) alendronate (Fosamax®): can cause esophageal ulcers. ℞ Prevention: 5 mg PO daily; treatment 10 mg PO daily; taken upright with water on an empty stomach at least 30 minutes before eating or drinking anything else. Once weekly dosing of 35 mg for prevention and 70 mg for treatment.[28,35] Taken concurrently with 1000–1500 mg/d Ca^{++} and 400/d IU of vitamin D
   c) risedronate (Actonel®): ℞ Prevention or treatment: 5 mg PO daily, or 35 mg once/week[35] on an empty stomach (as for alendronate, see above)
6. estrogen analogues:
   a) tamoxifen (Nolvadex®), an estrogen antagonist for breast tissue but an estrogen agonist for bone, has a partial agonist effect on uterus associated with an increased incidence of endometrial cancer
   b) raloxifene (Evista®): similar to tamoxifen but is an estrogen antagonist for uterus.[36] Decreases the effect of warfarin (Coumadin®).
   ℞: 60 mg PO q d. **Supplied:** 60 mg tablets
7. RANK ligand (RANKL) inhibitors: RANKL binds to RANK receptors and stimulates precursor cells to mature into osteoclasts and inhibits their apoptosis.[37] Includes denosumab (Prolia®) 60 mg SQ q 6 months (found to be more effective than alendronate[38])

Treatment of osteoporotic vertebral compression fractures

Patients rarely have neurologic deficit. They are also usually fragile elderly women who usually do not tolerate large surgical procedures well, and the rest of their bones are also osteoporotic which are poor for internal fixation.

Management consists primarily of analgesics and bed rest followed by progressive mobilization, often in an external brace (often not tolerated well). Surgery is rarely employed. In cases where pain control is difficult to obtain or where neural compression causes deficit, limited bony decompression may be considered. Percutaneous vertebroplasty (see below) is a newer option.

Typical time course of conservative treatment:

1. initially, severe pain may require hospital or subacute care facility admission for adequate pain control utilizing
   a) sufficient pain medication
   b) bed rest for about 7–10 days (DVT prophylaxis recommended)
2. begin physical therapy (PT) after ≈ 7–10 days as patient tolerates (prolonged bed rest can promote "disuse osteoporosis")
   a) pain control as patient is mobilized may be enhanced by a *lumbar brace*, which may work by reducing movement that causes repetitive "microfractures"
   b) discharge from the hospital with lumbar brace for outpatient PT
3. pain subsides on the average after 4–6 weeks (range 2–12 weeks)

Vertebral body augmentation

Percutaneous vertebroplasty (PVP)

Transpedicular injection of polymethylmethacrylate (PMMA) AKA "methylmethacrylate cement" into the compressed bone with the following goals (note: PMMA injection is FDA approved for treatment of compression fractures due to osteoporosis or tumor, but not for trauma, as PMMA would prevent healing of the fracture):

1. to shorten the duration of pain (sometimes providing pain relief within minutes to hours). Remember: the natural history is that pain will eventually diminish in essentially all of these patients. Mechanism of pain relief may be due to stabilization of bone and/or thermal damage to pain sensing nerves by heat released during the exothermic curing of the cement
2. to try and stabilize the bone: may prevent progression of kyphosis

Randomized studies published in 2009 found no benefit in vertebroplasty over a sham procedure at 1 month[39] or at any time up to 6 months post-procedure.[40] NB: kyphoplasty (see below) was not studied; use with metastatic spine tumors was also not evaluated. Patient selection issues may make these results more or less applicable to a specific patient.

Kyphoplasty

Similar to PVP, except first, a balloon is inserted into the compressed VB through the pedicle. The balloon is inflated and then deflated and removed. PMMA is injected into the thusly created defect. Potential benefits of this over vertebroplasty: there may be some restoration of height, and there may be less tendency for PMMA extravasation/embolization (due to the cavity creation and the thicker PMMA used). In the (industry-sponsored) randomized non-blinded FREE study[41] there was a significant positive difference in pain reduction and quality of life improvement in the kyphoplasty group compared to the nonoperated group at 1 month that diminished by 1-year post-op.

Indications

1. painful osteoporotic compression fractures:
   a) usually do not treat fractures producing < 5–10% loss of height
   b) severe pain that interferes with patient activity
   c) failure to adequately control pain with oral pain medication
   d) ★ pain localized to fracture level
   e) acute fractures: procedure is not effective for healed fractures. In questionable cases, look for increased signal on STIR MRI (▶ Fig. 81.7 panel C) (also see below)
2. levels: FDA approved for use from T5 through L5; however, has been used off-label (primarily for tumor, e.g., multiple myeloma) from T1 through sacrum, and has been described (for tumor) in the cervical spine from an anterior approach
3. some symptomatic vertebral hemangiomas (p. 992) e.g., those causing vertebral collapse or neurologic deficit as a result of extension into the spinal canal (not for incidental hemangiomas): the first indication for PVP[42]
4. osteolytic metastases and multiple myeloma[43]: pain relief and stabilization
5. pathologic compression fractures[44] from metastases: PVP does not give as rapid pain relief as with osteoporotic compression fractures (it may actually be necessary to increase pain meds for 7–10 days post PVP)
6. intraoperative pedicle screw salvage when pedicle fractures or screws strip during pedicle screw placement. Fenestrated pedicle screws allow injection of cement directly into the VB through perforations in the screw

Contraindications

1. coagulopathy
2. completely healed fractures (no edema on MRI or cold on bone scan, no focal point tenderness)
3. active infections: sepsis, osteomyelitis, discitis and epidural abscess
4. spinal instability: requires more than cement in the VB to stabilize
5. focal neurologic deficit: may indicate herniated disc, retropulsed fragment in canal. Get CT or MRI to rule these out
6. relative contraindications:
   a) fractures > 80% loss of VB height, e.g., vertebra planum (▶ Fig. 72.7). Technically challenging and often not possible to inject more than a very small amount of cement

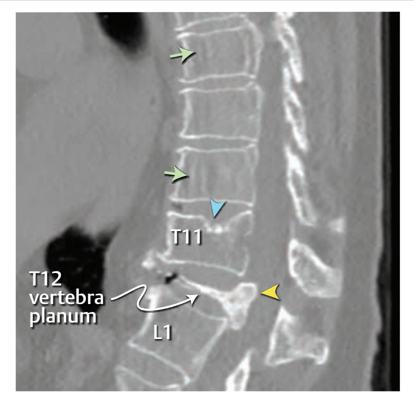

Fig. 72.7 Vertebra planum of T12.
Image: sagittal CT of thoracolumbar junction, bone window.
Near-complete collapse of T12 (vertebra planum) with bone retropulsed into the spinal canal (*yellow arrowhead*) in a 77-year-old woman with known osteoporosis (T-score = -3.6). Note vertical striations (some of which are indicated by *short green arrows*) indicative of osteoporosis and the mild superior endplate fracture of T11 (*blue arrowhead*).

   - b) significant canal compromise from tumor or retropulsed bone
   - c) partial or total destruction of the posterior VB wall: as with an acute burst fracture. Risk of cement leaking into spinal canal. Not an absolute contraindication, may be injected carefully with close fluoroscopic monitoring
7. iodine allergy: there is a small risk of a balloon rupturing with spill of the iodinated contrast used to fill the balloons prior to injecting the PMMA. Options include: iodine allergy prep (p. 232), use of gadolinium instead of iodinated contrast

Complications

Complication = rate: 1–9%. Lowest when used to treat osteoporotic compression fractures, higher with vertebral hemangiomas, highest with pathological fractures

1. methacrylate leakage:
   - a) into soft tissues: usually of little consequence
   - b) into spinal canal: symptomatic spinal cord compression is very rare
   - c) into neural foramen: may cause radiculopathy
   - d) into disc space
   - e) venous: can get into spinal venous plexus or vena cava with ≈ 0.3–1% risk of clinically significant methacrylate pulmonary embolism (PE)[45]
2. radiculopathy: 5–7% incidence. Some cases may be due to heat released during cement curing. Often treated conservatively: steroids, pain meds, nerve block…
3. pedicle fracture
4. rib fracture
5. transverse process fracture
6. anterior penetration with needle: puncture of great vessels, pneumothorax…
7. increased incidence of future VB compression fractures at adjacent levels

Management of some associated developments

1. chest pain
   - a) get rib X-rays
   - b) VQ scan if indicated
2. patient starts coughing during injection: fairly common. May be reaction to rib pain or to odor of PMMA, may also indicate solvent in lungs. Stop injecting
3. back pain: take X-ray to rule out new fracture or PMMA in veins
4. neurologic symptoms: get CT scan

Pre-procedure evaluation

1. plain X-rays: minimum requirement, most practitioners get MRI or bone scan
2. CT: helps rule out *bony* compromise of spinal canal, which may indicate increased risk of leakage for PMMA into canal during procedure
3. MRI: not mandatory, may be helpful in some cases
   - a) short tau inversion recovery (STIR) images (p. 241) demonstrate bone edema indicative of acute fractures (not as good for differentiating pathology)[46]
   - b) MRI can also disclose neurologic compression by *soft* tissue (e.g., tumor)
4. patients with multiple compression fractures: consider getting bone scan and perform PVP in the VB near the level of pain that lights up the most (↑ activity on bone scan correlates strongly with good outcome from PVP)

Booking the case: Kyphoplasty

Also see default values (p. 25).

1. position: prone
2. anesthesia: may be done under general, or under MAC
3. equipment: 2 C-arms for bi-plane fluoro
4. implants:
   - a) kyphoplasty set
   - b) iodinated contrast from radiology to fill balloons
5. consent (in lay terms for the patient—not all-inclusive):
   - a) procedure: insertion of a needle into the fractured/abnormal bone, sometimes getting a biopsy as well, and then inflating a balloon in the bone to try and bring it back to a more

normal size, and then injecting a liquid cement which will then harden inside the bone to strengthen it

b) alternatives: nonsurgical management, open surgery, in cases of tumor sometimes radiation therapy can be done

c) complications: leakage of cement which can compress nerves and may need to be removed surgically if possible, rib fracture (from positioning), injury to large blood vessel or lung by the needle, failure to achieve the desired pain relief

Procedure

1. pain medication
    a) remember, this procedure is done with the patient lying on their stomach and is usually performed on frail, elderly females who smoke. Therefore, use caution to avoid oversedation and respiratory compromise
    b) sedation and pain medication
    c) use of local anesthetic during needle placement
    d) additional pain medication just prior to injection
2. use bi-plane fluoro to pass needle through the pedicle to enter VB—see Percutaneous pedicle screws (p. 1797)—and place tip ≈ 1/2 to 2/3 of the way through the VB
3. test inject with contrast, e.g., iohexol (Omnipaque 300) (p. 230); do digital subtraction study if equipment is available. For kyphoplasty, the balloon is inflated at this time
    a) a little venous enhancement is acceptable
    b) if you visualize vena cava
        - do not pull needle back (the fistula has already been created)
        - push needle in a little further, or
        - push some gelfoam (soaked in contrast) through the needle, or
        - inject a very small amount of PMMA under visualization and allow it to set to block the fistula
4. inject PMMA (that has been opacified with tantalum or barium-sulfate) under fluoroscopic visualization until:
    a) 3–5 cc injected (minimal compression fractures accept more cement, sometimes up to ≈ 8 cc). No correlation between amount of PMMA injected and pain relief[43]
    b) PMMA approaches posterior VB wall. Stop if cement ever enters disc space, vena cava, pedicle, or spinal canal

Post-procedure

1. PVP is often an outpatient procedure, but sometimes overnight admission is used
2. watch for
    a) chest or back pain (may indicate rib fracture)
    b) fever: may be reaction to cement
    c) neurologic symptoms
3. activity
    a) gradual mobilization after ≈ 2 hours
    b) ± physical therapy
    c) ± short term use of external brace (most centers do not use)
4. institute medical treatment for osteoporosis: remember the patient with fragility fractures by definition has osteoporosis with risk of future fractures

72.4 Sacral fractures

72.4.1 General information

Uncommon. Usually caused by shear forces. Identified in 17% of patients with pelvic fractures[47] (∴ keep in mind that neurologic deficits in patients with pelvic fractures may be due to associated sacral fractures). Neurologic injuries occur in 22–60%.[47]

The sacrum below S2 is not essential to ambulation or support of the spinal column, but may still be unstable since pressure to the area may occur when supine or sitting.

72.4.2 Classification

Three characteristic clinical presentations based on zone of involvement[47,48] as shown in ▶ Table 72.7.

Table 72.7 Classification of sacral fractures

Zone I	Zone II	Zone III Vertical	Zone III Transverse
			Zone I: Region of ala sparing the central canal and neural foramina. Occasionally associated with partial L5 root injury, possibly as a result of entrapment of the L5 root between the upwardly migrated fracture fragment and the transverse process of the L5 vertebra	Zone II: Region of sacral foramina (sparing the central canal). A vertical fracture which may be associated with unilateral L5, S1, and/or S2 nerve root involvement (producing sciatica). Bladder dysfunction is rare	Zone III: Region of sacral canal. Frequently associated with sphincter dysfunction (occurs only with bilateral root injuries) and saddle anesthesia. Subdivided[47]:	
		vertical: almost always associated with pelvic ring fracture	transverse (horizontal): rare. Often due to a direct blow to the sacrum as in a fall from a great height. Marked displacement of fracture fragment can produce severe deficit[a] (bowel & bladder incontinence)

[a] significant deficit is rare in fractures at or below S4

A rare U-shaped Zone III fracture consists of bilateral longitudinal fractures connected by a transverse fracture at S2–3 (a weak area) producing a disconnection between the lumbosacral spine and the pelvis (▶ Fig. 72.8). It often occurs from falls from a height (called a "suicide jumper's fracture" by Roy-Camille[49]) but may also be seen with sacral insufficiency fractures (which are more typically "H" shaped). It is unstable and often produces a kyphotic deformity. Nerve compression or transection is common, with concomitant loss of bowel and bladder control. 3 sub-types:

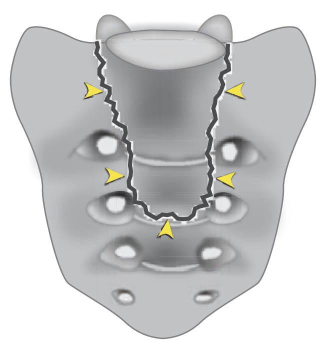

Fig. 72.8 U-shaped Zone III sacral fracture (*yellow arrowheads*).
Diagram of sacrum viewed from anterior perspective.

- Type 1: flexion fracture with anterior angulation of the upper fragment
- Type 2: flexion fracture with posterior displacement of the upper portion that perches almost horizontally on the lower fractur fragment
- Type 3: extension fracture with anterior displacement of the upper fragment

72.4.3 Treatment

In one series,[50] all 35 fractures were treated without surgery, and only 1 patient with a complete cauda equina syndrome did not improve. Others feel that surgery may have a useful role[47]:

1. operative reduction and internal fixation of unstable fractures may aid in pain control and promote early ambulation
2. decompression and/or surgical reduction/fixation may possibly improve radicular or sphincter deficits

Some observations[47]:

1. reduction of the ala may promote L5 recovery with Zone I fractures
2. Zone II fractures with neurologic involvement may recover with or without surgical reduction and fixation
3. horizontal Zone III with severe deficit: controversial. Reduction and decompression does not ensure recovery, which may occur with nonoperative management

► **U-shaped sacral fractures.** U-shaped sacral fractures are unstable and should be stabilized when possible. Percutaneous fixation may be performed with trans-iliac trans-sacral screws[51] (typically in conjunction with a surgeon experienced with pelvic stabilization). With this alone, the patient must be non-weight-bearing for 3 months. If this fixation is accompanied by posterior instrumented fusion from lumbar spine to pelvis (spino-pelvic AKA lumbo-pelvic fixation), the patient may begin weight-bearing immediately (► Fig. 72.9). If the anterior pelvis is also fractured, retrograde superior ramus screws AKA anterior column screws may be used to instrument that.

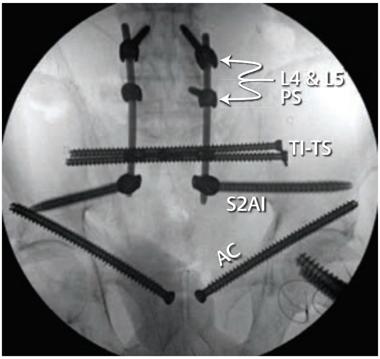

Fig. 72.9 Fixation of U-shaped Zone III sacral fracture.
AP X-ray. Abbreviations: AC = anterior column screws, PS = pedicle screws, S2A1 = S2-alar-iliac screws, TI-TS = trans-iliac trans-sacral screws.

73 Penetrating Spine Injuries and Long-Term Considerations of Spine Injuries

73.1 Gunshot wounds to the spine

73.1.1 General information

Most are due to assaults with handguns. Distribution: cervical 19–37%, thoracic 48–64%, and lumbosacral 10–29% (roughly proportional to lengths of each segment). Spinal cord injury due to civilian GSWs are primarily due to direct injury from the bullet (unlike military weapons which may create injury from shock waves and cavitation). Steroids are not indicated (p. 1140).

73.1.2 Indications for surgery

1. injury to the cauda equina (whether complete or incomplete) if nerve root compression is demonstrated[1]
2. neurologic deterioration: suggesting possibility of spinal epidural hematoma
3. compression of a nerve root
4. CSF leak
5. spinal instability: very rare with isolated GSW to the spine
6. to remove a copper jacketed bullet: copper can cause intense local reaction[2]
7. incomplete lesions: very controversial. Some series show improvement with surgery,[3] others show no difference from unoperated patients
8. debridement to reduce the risk of infection: more important for *military* GSW where there is massive tissue injury, not an issue for most civilian GSW except in cases where the bullet has traversed GI or respiratory tract
9. vascular injuries
10. surgery for late complications:
    a) migrating bullet
    b) lead toxicity[4] (plumbism): absorption of lead from a bullet occurs only when it lodges in joints, bursae, or *disc space*. Findings include: anemia, encephalopathy, motor neuropathy, nephropathy, abdominal colic
    c) late spinal instability: especially after surgery

73.2 Penetrating trauma to the neck

73.2.1 General information

Most often, injuries to the soft-tissues of the neck fall into the purvey of general/trauma surgeons and/or vascular surgeons. However, depending on local practice patterns, neurosurgeons may participate in care of these injuries, or they may get involved by virtue of associated spinal injuries (p. 1219).

The mortality rate for penetrating injury to the neck is ≈ 15%, with most early deaths due either to asphyxiation from airway compromise, or to exsanguination externally or into the chest or upper airways. Late death is usually due to cerebral ischemia or complications from spinal cord injury.

73.2.2 Vascular injuries

Venous injuries occur in ≈ 18% of penetrating neck wounds, and arterial injuries in ≈ 12%. Of the cervical arteries, the common carotid is most usually involved, followed by the ICA, the ECA, and then the vertebral artery. Outcome probably correlates most closely with neurologic condition on admission, regardless of treatment.

Vertebral artery (VA): the majority of injuries are penetrating. Due to the proximity of other vessels, the spinal cord and nerve roots, injuries are rarely isolated to the VA. 72% of documented VA injuries had no related physical findings on exam.[5]

73.2.3 Classification

Trauma surgeons have traditionally divided penetrating injuries of the neck into 3 zones,[6] and although definitions vary, the following is a general scheme[7]:

Zone I: inferiorly from the head of the clavicle to include the thoracic outlet.
Zone II: from the clavicle to the angle of the mandible.
Zone III: from the angle of the mandible to the base of the skull.

73.2.4 Evaluation

Neurologic examination: global deficits may be due to shock or hypoxemia due to asphyxiation. Cerebral neurologic deficits are usually due to vascular injury with cerebral ischemia. Local findings may be related to cranial nerve injury. Unilateral UE deficits may be due to nerve root or brachial plexus involvement. Median or ulnar nerve dysfunction can occur from compression by a pseudoaneurysm of the proximal axillary artery. Spinal cord involvement may present with complete injury, or with an incomplete spinal cord injury syndrome (p. 1132). Shock due to spinal cord injury is usually accompanied by bradycardia (p. 1119), as opposed to the tachycardia seen with hypovolemic shock.

Cervical spine X-rays: assesses trajectory of injury and integrity of C-spine.

Angiography: indicated in most cases if the patient is stable (especially for zone I or III injuries, and for zone II patients with no other indication for exploration, or for patients with penetration of the posterior triangle or wounds near the transverse processes where the VA may be injured). Patients actively hemorrhaging need to be taken to the OR without pre-op angiography. Angiographic abnormalities include:

1. extravasation of blood
   a) expanding hematoma into soft tissues: may compromise airway
   b) pseudoaneurysm
   c) AV fistula
   d) bleeding into airways
   e) external bleeding
2. intimal dissection, with
   a) occlusion, or
   b) luminal narrowing (including possible “string sign”)
3. occlusion by soft tissue or bone

73.2.5 Treatment

Airway

Stable patients without airway compromise should not have “prophylactic” intubation to protect the airway. Immediate intubation is indicated for hemodynamically unstable patients or for airway compromise. Options:

- endotracheal: preferred
- cricothyroidotomy: if endotracheal intubation cannot be performed (e.g., due to tracheal deviation or patient agitation) or if there is evidence of cervical spine injury and manipulation of the neck is contraindicated, then cricothyroidotomy is performed with placement of a #6 or 7 cuffed endotracheal tube (followed by a standard tracheostomy in the OR once the patient is stabilized)
- awake nasotracheal: may be considered in the setting of possible spinal injury

Indications for surgical exploration

Surgical exploration has been advocated for all wounds that pierce the platysma and enter the anterior triangles of the neck[8]; however, 40–60% of these explorations will be negative. Although a selective approach may be based on angiography, false negatives have resulted in some authors recommending exploration of all zone II injuries.[9]

Surgical treatment for vascular injuries

Endovascular techniques may be suitable for select cases, especially for patients who are already in the endovascular suite for angiography. However, patients who are actively bleeding usually end up in the O.R. with an open procedure.

Carotid artery: choices are primary repair, interposition grafting, or ligation. Patients in coma or those with severe strokes caused by vascular occlusion of the carotid artery are poor surgical candidates for vascular reconstruction due to a high mortality rate ≥ 40%[7]; however, the outcome with ligation is worse. Repair of injuries is recommended in patients with no or only minor neurologic deficit. ICA ligation is recommended for bleeding that cannot be controlled and was used for extravasation of dye at the base of the skull in 1 patient.[10]

Vertebral artery: injuries are more often managed by ligation than by direct repair,[11] especially when bleeding occurs during exploration. Less urgent conditions (e.g., AV fistula) require knowledge of the patency of the contralateral VA and the ability to fill the ipsilateral PICA from retrograde flow through the BA before ligation can be considered (arteriographic anomalies contraindicate ligation in 15% of cases). Proximal occlusion may be accomplished with an anterior approach after the sternocleidomastoid is detached from the sternum. The VA is normally the first branch of the subclavian artery. Alternatively, endovascular techniques may be used, e.g., detachable balloons for proximal occlusion, or thrombogenic coils for pseudoaneurysms. Distal interruption may also be required, and this necessitates surgical exposure and ligation. Optimal management of a thrombosed injured VA in a foramen transversarium is unknown, and may require arterial bypass if ligation is not a viable option.

73.3 Delayed cervical instability

73.3.1 General information

Definition (adapted[12]): cervical instability (p. 1118) that is not recognized until beyond 20 days after the injury. The instability itself may be delayed, or the recognition may be delayed.

73.3.2 Etiologies

Reasons for delayed cervical instability:

1. inadequate radiologic evaluation[13]
    a) incomplete studies (e.g., must see all the way down to C7–1 junction)
    b) suboptimal studies: motion artifact, incorrect positioning… Etiologies include: poor patient cooperation as a result of agitation/intoxication, portable films, poor technique…
2. abnormality missed on X-ray
    a) overlooked fracture, subluxation
    b) injury failed to be demonstrated despite sufficiently adequate X-rays[12]; see recommendations of extent of radiologic workup (p. 1301)
        - type of fracture not demonstrated on the radiographs obtained
        - patient positioning (e.g., supine) may reduce some malalignment
        - spasm of cervical muscles may reduce and/or stabilize the injury
        - microfractures
3. inadequate models: some findings may be judged to be stable using certain models, but in the long-run may prove to be unstable (there is no perfect model for instability)

73.3.3 Indications for additional studies

Further studies or repeat X-rays several weeks after the trauma should be considered in patients with neurologic deficit, persistent pain, significant degenerative changes when the original films were suboptimal, subluxations < 3 mm, or when surgery is contemplated.[14]

73.4 Delayed deterioration following spinal cord injuries

Etiologies include:

1. posttraumatic syringomyelia (p. 1411). Latency to symptoms: 3 mos–34 yrs
2. subacute progressive ascending myelopathy (SPAM): rare. Median time of occurrence: 13 days post injury (range: 4–86 days).[15] Signal changes extending to ≥ 4 levels above the original injury
3. unrecognized spinal instability[16]: mean delay in diagnosis was 20 days
4. tethered spinal cord: may be due to scar tissue at site of injury
5. delayed spinal epidural hematoma (SEH): most symptomatic SEH occur within 72 hours of surgery; however, longer delays have been reported[17]
6. apoptosis of neurons, oligodendrogliocytes, and astrocytes[18]: initiated during the acute phase, deterioration occurs during the chronic phase of SCI (months to years after SCI)
7. glial scar formation: mass effect as well as release of factors that may damage surviving neurons[19(p 43–5)]

73.5 Chronic management issues with spinal cord injuries

73.5.1 Overview

Most of the following topics are treated elsewhere in this handbook, but are pertinent to spinal cord injured (SCI) patients, and reference to the specific section is made.

- autonomic hyperreflexia: see below
- ectopic bone, includes para-articular heterotopic ossification: ossification of some joints that occurs in 15–20% of paralyzed patients
- osteoporosis and pathologic fracture (p. 1209)
- spasticity (p. 1845)
- syringomyelia (p. 1405)
- deep vein thrombosis (p. 1141): see below
- shoulder-hand syndrome: possibly sympathetically maintained

73.5.2 Respiratory management problems in spinal cord injuries

In attempting to wean high-level SCI patients from a ventilator, it may be helpful to change tube feedings to Pulmonaid® which lowers the CO_2 load.

Patients with cervical SCIs are more prone to pneumonia due to the fact that most of the effort in a normal cough originates in the abdominal muscles which are paralyzed.

73.5.3 Autonomic hyperreflexia

General information

Key concepts

- exaggerated autonomic response to normally innocuous stimuli
- in spinal cord injury, occurs only in patients with lesions above ≈ T6
- patients complain of pounding headache, flushing, and diaphoresis above lesion
- can be life-threatening, requires rapid control of hypertension and a search for an elimination of offending stimuli

AKA autonomic dysreflexia. Autonomic hyperreflexia[20,21] (AH) is an exaggerated autonomic response (sympathetic usually dominates) secondary to stimuli that would only be mildly noxious under normal circumstances. It occurs in ≈ 30% of quadriplegic and high paraplegic patients (reported range is as high as 66–85%), but does not occur in patients with lesions below T6 (only patients with lesions above the origin of the splanchnic outflow are prone to develop AH, and the origin is usually T6 or below). It is rare in first 12–16 weeks post-injury.

During attacks, norepinephrine (NE) (but not epinephrine) is released. Hypersensitivity to NE may be partially due to subnormal resting levels of catecholamines. Homeostatic responses include vasodilatation (above the level of the injury) and bradycardia (however, sympathetic stimulation may also cause tachycardia).

Stimuli sources

Stimulus sources causing episodes of autonomic hyperreflexia:

1. bladder: 76% (distension 73%, UTI 3%, bladder stones…)
2. colorectal: 19% (fecal impaction 12%, administering enema or suppository 4%)
3. decubitus ulcers/skin infection: 4%
4. DVT
5. miscellaneous: tight clothing or leg bag straps, procedures such as cystoscopy or debriding decubitus ulcers, case report of suprapubic tube

Presentation

1. paroxysmal HTN: 90%
2. anxiety
3. diaphoresis

4. piloerection
5. pounding H/A
6. ocular findings:
   a) mydriasis
   b) blurring of vision
   c) lid retraction or lid lag
7. erythema of face, neck, and trunk: 25%
8. pallor of skin below the lesion (due to vasoconstriction)
9. pulse rate: tachycardia (38%) or mild elevation over baseline, bradycardia (10%)
10. "splotches" over face and neck: 3%
11. muscle fasciculations
12. increased spasticity
13. penile erection
14. Horner syndrome
15. triad seen in 85%: cephalgia (H/A), hyperhidrosis, cutaneous vasodilatation

Evaluation

In the appropriate setting (e.g., a quadriplegic patient with an acutely distended bladder), the symptoms are fairly diagnostic.

Many features are also common to pheochromocytoma. Studies of catecholamine levels have been inconsistent; however, they can be mildly elevated in AH. The distinguishing feature of AH is the presence of hyperhidrosis and flushing of the face in the presence of pallor and vasoconstriction elsewhere on the body (which would be unusual for a pheochromocytoma).

Treatment

1. immediately elevate HOB (to decrease ICP), check BP q 5 min
2. treatment of choice: identify and eliminate the offending stimulus
   a) make sure bladder is empty (if catheterized check for kinks or sediment plugs). Caution: irrigating bladder may exacerbate AH (consider suprapubic aspiration)
   b) check bowels (avoid rectal exam, may exacerbate). Palpate abdomen or check abdominal X-ray (AH from this usually resolves spontaneously without manual disimpaction)
   c) check skin and toenails for ulceration or infection
   d) remove tight apparel
3. HTN that is extreme or that does not respond quickly may require treatment to prevent seizures and/or cerebral hemorrhage/hypertensive encephalopathy. Caution must be used to prevent hypotension following the episode. Agents used include: sublingual nifedipine[22] 10 mg SL, IV phentolamine—alpha cholinergic blocker (p. 943)—or nicardipine (p. 131).
4. consider diazepam (Valium®) 2–5 mg IVP (@ < 5 mg/min). Relieves spasm of skeletal and smooth muscle (including bladder sphincter). Is also anxiolytic

Prevention

Good bowel/bladder and skin care are the best preventative measures.

Prophylaxis in patients with recurrent episodes:

- *phenoxybenzamine* (Dibenzyline®): an alpha-blocker. Not helpful during the acute crisis. May not be as effective for alpha stimulation from sympathetic ganglia as with circulating catecholamines.[23] The patient may also develop hypotension after the sympathetic outflow subsides. Thus this is used only for resistant cases (note: will not affect sweating, which is mediated by acetylcholine).
  ℞ Adult: wide range quoted in literature: average 20–30 mg PO BID
- beta-blockers: may be necessary in addition to α-blockers to avoid possible hypotension from β_2-receptor stimulation (a theoretical concern)
- phenazopyridine (Pyridium®): a topical anesthetic that is excreted in the urine. May decrease bladder wall irritation; however, the primary cause of irritation should be treated if possible.
  ℞ Adult: 200 mg PO TID after meals. **Supplied:** 100, 200 mg tabs.
- "radical measures" such as sympathectomy, pelvic or pudendal nerve section, cordectomy, or intrathecal alcohol injection have been advocated in the past, but are rarely necessary and may jeopardize reflex voiding

- prophylactic treatment prior to procedures may employ use of anesthetics even in regions rendered anesthetic by the cord injury. Nifedipine 10 mg SL has also been used effectively for AH during cystoscopy and prophylactically[22]

74 Low Back Pain

74.1 Low back pain – general information

Key concepts

- low back pain is common, and in ≈ 85% of cases no specific diagnosis can be made[1]
- initial assessment is geared to detecting "red flags" (indicating potentially serious pathology), and in the absence of these, imaging studies and further testing of patients is usually not helpful during the first 4 weeks of low back symptoms
- relief of discomfort is usually best achieved with nonprescription pain medications and/or spinal manipulation
- while activities may need to be modified, bed rest beyond 4 days may be more harmful than helpful, and patients are encouraged to return to work or their normal daily activities as soon as possible
- 89–90% of patients with low back problems will improve within 1 month even without treatment (including patients with sciatica from disc herniation)

Σ: Simplified outline for initial management of acute LBP

(see details in text)

1. emergency: if any of these factors are present the patient should go to an emergency room
   a) progressive neurologic deficit (e.g., weakness)
   b) cauda equina syndrome (p. 1254) (includes bladder issues, saddle anesthesia…)
   c) intractable pain
2. absent these emergency conditions, conservative treatment measures should be employed during the first 4-6 weeks after onset of low back pain, and include
   a) manipulation therapy: e.g., PT or chiropractic
   b) analgesics (p. 1237) (with minimal opioid use)
   c) sometimes: interventional pain management (e.g., epidural steroid injections)
3. if the pain persists > 4 weeks, obtaining an MRI is appropriate option
4. referral to specialty care (i.e., spine surgeon) is appropriate if the MRI identifies a surgically treatable condition such as a herniated disc

Low back pain (LBP) is extremely prevalent, and is the second most common reason for people to seek medical attention.[2] After the common cold, it is the number two cause for loss of time at work. LBP accounts for ≈ 15% of all sick leave from work, and is the most common cause of disability for persons < 45 yrs of age.[3] Estimates of lifetime prevalence range from 60–90%, and the annual incidence is 5%.[4] Only 1% of patients will have nerve-root symptoms, and only 1–3% have lumbar disc herniation. The prognosis for most cases of LBP is good, and improvement usually occurs with little or no medical intervention.

74.2 Intervertebral disc

74.2.1 General information

The function of the intervertebral disc is to permit stable motion of the spine while supporting and distributing loads under movement. The intervertebral disc has been characterized as the largest nonvascularized structure in the human body, which imparts some unique attributes to it.

74.2.2 Anatomy

Anulus fibrosus (anulus may alternatively be spelled annulus, but fibrosus is the only correct spelling and is distinct from fibrosis)[5]: the multilaminated ligament that encompasses the periphery of the disc space. Attaches to the endplate cartilage and ring apophyseal bone. Blends centrally with the nucleus pulposus.

Nucleus pulposus: the central portion of the disc. A remnant of the notocord.

Capsule[5]: combined fibers of the anulus fibrosus and the posterior longitudinal ligament (this term is useful because these 2 structures may not be distinguishable on imaging studies).

74.2.3 Nomenclature for disc pathology

Historically, the terminology for lumbar disc pathology has been contentious and nonstandardized. A committee tasked to standardize the nomenclature has issued version 2.0 of their recommendations.[6] Some of these standardizations are useful primarily for consistency related to radiographic reports and for research, and may not be as useful for day-to-day clinical practice. A subset of the recommendations is shown in ▶ Table 74.1.

Degenerated disc: (see ▶ Table 74.1 for definition) some contend that these can cause radicular pain possibly by an inflammatory mechanism,[7] but this is not universally accepted.

Vacuum disc: gas in the disc space (empty space on imaging, e.g., as shown in ▶ Fig. 81.8 **A**), usually indicates disc degeneration, *not* infection. Levels with vacuum disc are often hypermobile and are therefore usually more amenable to surgical manipulation.

Table 74.1 Nomenclature for lumbar disc pathology[6]

Term	Description
anular tears AKA anular fissures	separations between anular fibers, avulsions of fibers from their VB insertions, or breaks through fibers that extend radially, transversely, or concentrically
degeneration	desiccation, fibrosis, narrowing of the disc space, diffuse bulging of the anulus beyond the disc space, extensive fissuring (numerous anular tears), mucinous degeneration of the anulus, defects & sclerosis of endplates, & osteophytes at the vertebral apophyses
degenerative disc disease	clinical syndrome of symptoms related to degenerative changes in the intervertebral disc (described above), also often considered to encompass degenerative changes outside the disc as well
bulging disc	generalized displacement of disc material (arbitrarily defined as > 50% or 180°) beyond the peripheral limits of the disc space. Not considered a form of herniation. May be a normal finding, not usually symptomatic
herniation	localized displacement of disc material (< 50% or 180°) beyond the limits of the intervertebral disc space
	focal: < 25% of the disc circumference
	broad-based: 25–50% of the disc circumference
	protrusion: the fragment does not have a “neck” that is narrower than the fragment in any dimension
	extrusion: the fragment has a “neck” that is narrower than the fragment in at least 1 dimension. 2 subtypes: a) sequestration: the fragment has lost continuity with the disc of origin (AKA free fragment) b) migration: the fragment is displaced away from the site of extrusion, regardless of whether sequestered or not
	intravertebral herniation (AKA Schmorl’s node (p. 1266)): disc herniates in the cranio-caudal direction through the cartilaginous endplate into the VB

74.3 Clinical terms

▶ **Radiculopathy.** Dysfunction of a nerve root; signs and symptoms may include: pain in the distribution of that nerve root, dermatomal sensory disturbances, weakness of muscles innervated by that nerve root, and hypoactive muscle stretch reflexes of the same muscles.

▶ **Mechanical low back pain** (p. 1226). AKA “musculoskeletal” back pain (both non-specific terms). The most common form of low back pain. May result from strain of the paraspinal muscles and/or ligaments, irritation of facet joints… Excludes anatomically identifiable causes (e.g., tumor, disc herniation…).

▶ **Sciatica.** Pain along the course of the sciatic nerve, usually resulting from nerve root compromise (the sciatic nerve is composed of nerve roots L1 through S3).

74.4 Disability, pain, and outcome determinations

Disability scales for low back pain have been developed to assess outcomes for research purposes. Some widely used measures include:

1. visual analogue scale: used for any type of pain. The patient is asked to mark their pain level on a line divided into segments with sequential labels 0 (no pain) to 10 (the worst pain)
2. Oswestry disability index (ODI)[8]: a categorical ordinal scale that is used for low back pain. There are 4 English versions in wide use[9]; version 2.0[10] is recommended.[9]
   It consists of 10 questions related to activities of daily living. Each item is scored 0–5 (5 being the most disability) and the total is multiplied by 2% to obtain the final score (range: 0–100%). The interpretation of the final score is shown in ▶ Table 74.2. A score > 45% is essentially completely disabled. A score in the teens is very functional
3. Roland–Morris disability questionnaire[11]
4. Short Form 36 (SF36)[12]

Table 74.2 Oswestry disability index score

Score	Interpretation
0–20%	minimal disability: can cope with most daily activities
21–40%	moderate disability: pain and difficulty with sitting, lifting, and standing. The patient may be disabled from work
41–60%	severe disability: pain is the main problem, but other areas are affected
61–80%	crippled: back pain impinges on all aspects of the patient's life
81–100%	these patients are either bed-bound or else are exaggerating their symptoms

74.5 Differential diagnosis of low back pain

The differential diagnosis of low back pain (p. 1226) overlaps with that of myelopathy. In ≈ 85% of cases of LBP no specific diagnosis can be made[13]; however, serious and/or dangerous conditions can usually be reliably ruled out.

74.6 Initial assessment of the patient with back pain

74.6.1 Background

Initial assessment consists of a history and physical exam focused on identifying serious underlying conditions such as: fracture, tumor, infection, or cauda equina syndrome (p. 1254). Serious conditions presenting as low back problems are relatively rare.

74.6.2 History

The following information has been found to be helpful in identifying patients with serious underlying conditions such as cancer and spinal infection.[1]

1. age
2. history of cancer (especially malignancies that are prone to skeletal metastases: prostate, breast, kidney, thyroid, lung, lymphoma/myeloma)
3. unexplained weight loss
4. immunosuppression: from steroids, organ transplant medication, or HIV
5. prolonged use of steroids
6. duration of symptoms
7. responsiveness to previous therapy
8. pain that is worse at rest
9. history of skin infection: especially furuncle
10. history of IV drug abuse
11. UTI or other infection
12. pain radiating below the knee

13. persistent numbness or weakness in the legs
14. history of significant trauma. In a young patient: usually involves MVA, a fall from a height, or a direct blow to the back. In an older patient: minor falls, heavy lifting, or even a severe coughing episode can cause a fracture especially in the presence of osteoporosis
15. findings consistent with cauda equina syndrome (p. 1254):
    a) bladder dysfunction (usually urinary retention, or overflow incontinence) or fecal incontinence
    b) saddle anesthesia (p. 1254)
    c) unilateral or bilateral leg weakness or pain
16. psychological and socioeconomic factors (p. 1236) may influence the patient's report of symptoms, and one should inquire about:
    a) work status
    b) typical job tasks
    c) educational level
    d) pending litigation
    e) worker's compensation or disability issues
    f) failed previous treatments
    g) substance abuse
    h) depression
    i) domestic violence
    j) homelessness

▶ Table 74.3 shows the sensitivity and specificity of some features of the history for various conditions.

Table 74.3 Sensitivity and specificity of historical findings in patients with low back problems[1]

Condition	History	Sensitivity	Specificity
cancer	age ≥ 50 yrs	0.77	0.71
	previous cancer	0.31	0.98
	unexplained weight loss	0.15	0.94
	failure to improve after conservative therapy × 1 month	0.31	0.90
	any of the above	1.00	0.60
	pain > 1 month	0.50	0.81
spinal osteomyelitis	IV drug abuse, UTI, or skin infection	0.40	NA
compression fracture	age ≥ 50 yrs	0.84	0.61
	age ≥ 70 yrs	0.22	0.96
	trauma	0.30	0.85
	steroid use	0.06	0.995
HLD	sciatica	0.95	0.88
spinal stenosis	pseudoclaudication	0.60	NA
	age ≥ 50 yrs	0.90[a]	0.70
ankylosing spondylitis	positive response to 4 out of 5 of the following	0.23	0.82
	age at onset ≤ 40 yrs	1.00	0.07
	pain not relieved when supine	0.80	0.49
	morning back stiffness	0.64	0.59
	pain ≥ 3 mos duration	0.71	0.54

[a] estimate

74.6.3 Physical examination

Less helpful than the history in identifying patients who may be harboring conditions such as cancer, but may be more helpful in detecting spinal infections.

1. spinal infection (p. 380): findings that suggest this as a possibility (but are also common in patients without infection)
   a) fever: common in epidural abscess and vertebral osteomyelitis, less common in discitis
   b) vertebral tenderness
   c) very limited range of spinal motion
2. findings of possible neurologic compromise: the following physical findings will identify most cases of clinically significant nerve root compromise due to L4–5 or L5–1 HLD, which comprise > 90% of cases of radiculopathy due to HLD; limiting the exam to the following might not detect the much less common upper lumbar disc herniations, which may be difficult to detect on PE (p. 1263)
   a) dorsiflexion strength of ankle and great toe: weakness suggests L5 and some L4 dysfunction
   b) achilles reflex: diminished reflex suggests S1 root dysfunction
   c) light touch sensation of the foot:
      - diminished over medial malleolus and medial foot: suggests L4 nerve root involvement
      - diminished over dorsum of foot: suggests L5
      - diminished over lateral malleolus and lateral foot: suggests S1
   d) straight leg raising (SLR); also check for crossed SLR (p. 1252)

74.6.4 “Red flags” in the history and physical exam for low back problems

Based upon the above history and physical exam, the findings in ▶ Table 74.4 would suggest the possibility of a serious underlying condition as the cause of the low back problem. Also, thoracic region pain is relatively uncommon and should raise the index of suspicion.

Table 74.4 “Red flags” for patients with low back problems

Condition	Red flags
cancer or infection	1. age > 50 or < 20 yrs 2. history of cancer 3. unexplained weight loss 4. immunosuppression (see text) 5. UTI, IV drug abuse, fever, or chills 6. back pain not improved with rest
spinal fracture	1. history of significant trauma (see text) 2. prolonged use of steroids 3. age > 70 yrs
cauda equina syndrome or severe neurologic compromise	1. acute onset of urinary retention or overflow incontinence 2. fecal incontinence or loss of anal sphincter tone 3. saddle anesthesia 4. global or progressive weakness in the LEs

74.6.5 Special diagnostic tests

For patients without features suggesting a serious underlying condition, special diagnostic tests are not needed during the first month of symptoms. This covers approximately 95% of patients with low back problems.[1]

74.7 Radiographic evaluation

74.7.1 General information

Diagnosing lumbar spinal stenosis or herniated intervertebral disc is usually helpful only in potential surgical candidates.[14] This includes patients with appropriate clinical syndromes who have not responded satisfactorily to adequate non-surgical treatment over a sufficient period of time, and who have no medical contraindications to surgery. Radiologic confirmation of these diagnoses usually requires MRI, CT, myelography, or some combination (see below). NB: myelography,[15] CT,[16] or MRI[17] may also show bulging or herniated lumbar discs (HLD) or spinal stenosis in *asymptomatic* patients (e.g., 24% of asymptomatic patients have herniated discs on MRI and 4% have spinal stenosis; these numbers become 36% and 21% respectively in patients 60–80 years old).[18] Thus, these tests must be interpreted in light of clinical findings, and the anatomic level and side should correspond to the history, examination, and/or other physiologic data. Diagnostic radiology is of limited benefit as the initial evaluation in the majority of spinal disorders.[19]

In the absence of red flags for serious conditions, imaging studies are not recommended in the first month of symptoms.[1] For patients who have had previous back surgery, MRI with contrast is probably the best test. Myelography (with or without CT) is invasive and has increased risk of complications, and is therefore indicated only in situations where MRI cannot be done or is inadequate, and the possibility of surgery is anticipated.

Σ: Patients for whom radiographic imaging is recommended

Patients with:

1. suspected *benign* conditions with symptoms persisting > 4 weeks of great enough severity to consider surgery, including:
    a) back-related leg symptoms and clinically specific signs of nerve root compromise
    b) a history of neurogenic claudication (p. 1331) or other findings suggestive of lumbar spinal stenosis
    c) symptoms related to spinal deformity/imbalance, especially positional back pain that increases with time spent upright
2. red flags: physical examination or other test results suggesting other serious conditions affecting the spine (e.g., cauda equina syndrome, fracture, infection, tumor, or other mass lesions or defects)

Recommendations for use of MRI and discography to select patients for **fusion** are shown in the Practice Guideline (p. 1231).

Practice guideline: MRI and discography for patient selection for lumbar fusion*

1. **Level II**[20]:
    a) MRI is recommended as the initial diagnostic test
    b) normal appearing discs on MRI should not be considered for discography or treatment
    c) lumbar discography should not be used as a stand-alone test
    d) to consider a disc level for treatment, if discography is used, there should be a concordant pain response[a] and associated abnormalities on MRI[b]
2. **Level III**[20]: discography should be reserved for equivocal MRI findings, especially at levels adjacent to unequivocally abnormal levels

Notes:

* see also recommendations on use of facet injections (p. 1239)

[a] concordant pain response: pain identical or very similar to the patient's usual pain complaints (NB: discography can produce severe LBP in patients with no prior complaints[21,22])

[b] abnormal disc morphology on MRI: loss of T2WI signal intensity ("black disc"), disc space collapse, Modic changes (see ▶ Table 81.5), and high-intensity zones (these findings also frequently occur in asymptomatic patients[23])

74.7.2 Plain lumbosacral X-rays

General information

Unexpected findings occurred in only 1 in 2500 adults < 50 years of age.[24] Diagnosis of surgical conditions of disc herniation and spinal stenosis cannot be made from plain films (although they may be inferred, further study would be required). Various congenital abnormalities of uncertain significance may be identified (e.g., spina bifida occulta), and evidence of degenerative changes (including osteophytes) are as frequent in symptomatic as in asymptomatic patients. Gonadal radiation is significant. Seldom indicated during pregnancy.

Recommendation

Not recommended for routine evaluation of patients with acute low back problems during the first month of symptoms unless a "red flag" is present (see below). Reserve LS X-rays for patients with a likelihood of having spinal malignancy, infection, inflammatory spondylitis, or clinically significant fracture. In these cases, plain X-rays are often just a starting point, and further study (CT, MRI…) may be indicated even if the plain X-rays are normal. "Red flags" for these conditions include the following:

- age > 70 yrs, or < 20 yrs
- systemically ill patients
- temp > 100 °F (or > 38 °C)
- history of malignancy
- recent infection
- patients with neurologic deficits suggesting possible cauda equina syndrome (p. 1254) (saddle anesthesia, urinary incontinence or retention, LE weakness)
- heavy alcohol or IV drug abusers
- diabetics
- immunosuppressed patients (including prolonged treatment with corticosteroids)
- recent urinary tract or spinal surgery
- *recent* trauma: any age with significant trauma, or > 50 yrs old with mild trauma
- unrelenting pain at rest
- persistent pain for more than ≈ 4 weeks
- unexplained weight loss

When spine X-rays are indicated, AP and lateral views are usually adequate.[25] Obliques and coned-down L5–1 views more than double the radiation exposure, and add information in only 4–8% of cases,[26] and can be obtained in specific instances where warranted (e.g., to diagnose spondylolysis when spondylolisthesis is found on the lateral film).

Specialized X-ray views

► **Flexion/extension lumbar spine X-rays.** Lateral X-rays taken with the patient in neutral position, then while flexing forward at the waist, then with hyperextension at the waist. May demonstrate "dynamic instability" (► Fig. 74.1) which may not be evident on static views (including CT and MRI obtained with the patient recumbent), and which may factor into decisions regarding fusion during lumbar spinal surgery.

► **Oblique X-rays.** Demonstrates spondylolysis as a fracture in the neck of the "Scotty dog." Utilized less frequently since CT scan demonstrates this with greater detail and accuracy (the pars defect is sometimes difficult to appreciate on MRI).

► **Standing scoliosis X-rays.** Primary indication is in preparation for surgical intervention (p. 1353).

74.7.3 Lumbosacral CT

If technically adequate images can be obtained (e.g., good quality scanner, images not obscured by artifact from patient movement or obesity), CT can demonstrate most spine pathology. For HLD, sensitivity is 80–95%, and specificity is 68–88%.[29,30] However, even some large disc herniations will be missed with plain CT. CT studies for HLD tend to be less satisfactory in the elderly. When MRI is an option, the main utility of CT is for imaging bone to assess fractures or to demonstrate details of bony anatomy for surgery.

Disc material has density (Hounsfield units) ≈ twice that of the thecal sac. Associated findings with herniated disc include:

- loss of epidural fat (normally seen as low density in the anterolateral canal)
- loss of normal "convexity" of thecal sac (indentation by herniated disc)

Advantages:

- excellent bony detail
- non-invasive
- outpatient evaluation
- evaluates paraspinal soft tissue (e.g., to rule out tumor, paraspinal abscess…)
- advantages over MRI: faster scanning (significant in patients who have difficulty lying still for a long time), less expensive, less claustrophobic, fewer contraindications, see Contraindications to MRI (p. 242)

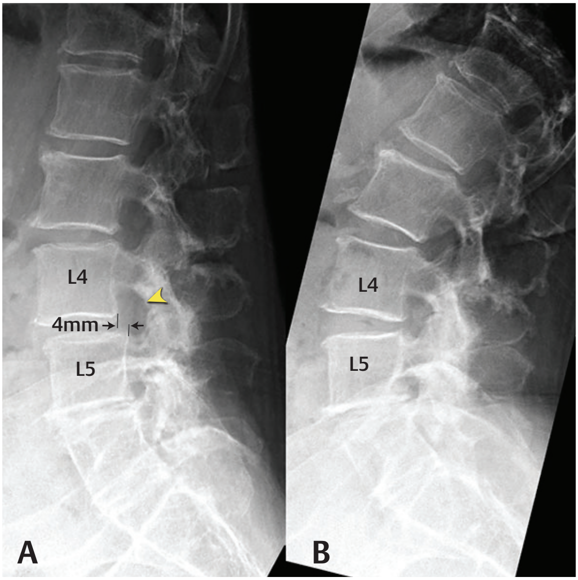

Fig. 74.1 Instability on lateral lumbar spine flexion/extension X-rays. Image: A: flexion, and B: extension, demonstrating dynamic instability at L4–5 with 4 mm of anterolisthesis of L4 on L5 in flexion that reduces in extension. This was not evident on lumbar MRI nor on neutral position lateral X-rays. Note the accompanying change in configuration of the neural foramen (*yellow arrowhead*) between the two views.

Disadvantages:

- involves ionizing radiation (X-rays)
- sensitivity is significantly lower than MRI or myelogram/CT

74.7.4 MRI

Unless contraindicated, noncontrast MRI is the initial diagnostic test of choice for diagnosing most cases of disc herniation and spinal stenosis. Specificity and sensitivity for HLD are on the same order as CT/myelography, which is better than myelography alone.[1,31,27]

Advantages:

- provides the most information about soft tissues (intervertebral discs, spinal cord, inflammation…) of any available diagnostic test
- provides information regarding tissue outside of the spinal canal, e.g., extreme lateral disc herniation (p. 1263), tumors…
- non-invasive and does not utilize ionizing radiation

Disadvantages:

- patients in severe pain or with claustrophobia may have difficulty holding still
- does not visualize bone well
- poor for studying blood early (e.g., spinal epidural hematoma)
- expensive
- interpretation with scoliosis is more difficult, may be partially compensated by contouring visualization plane through center of canal
- a number of contraindications to MRI: see Contraindications to MRI (p. 242)

Findings:

In addition to demonstrating herniated lumbar disc (HLD) outside of the disc interspace compressing nerve root or thecal sac (▶ Fig. 74.2), MRI can demonstrate signal changes of the disc within the interspace suggestive of *disc degeneration*[28] (loss of signal intensity on T2WI, loss of disc space height) as well as endplate changes (see Modic classification (p. 1335)) and is useful in diagnosing infections and tumors.

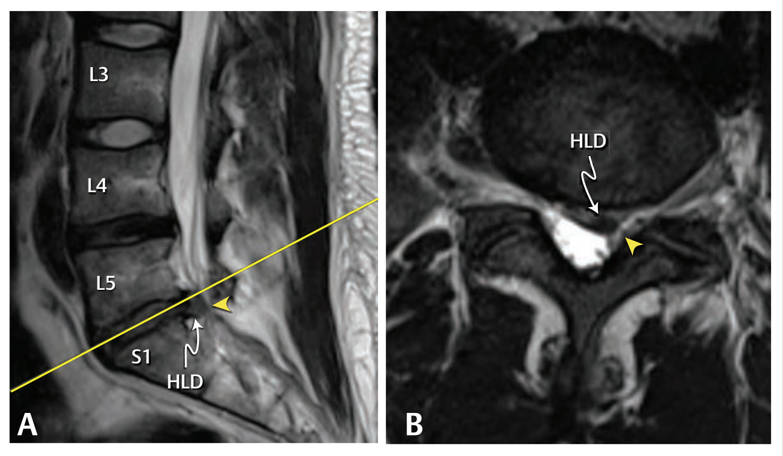

Fig. 74.2 Left-sided herniated lumbar disc (HLD).
Image: MRI, A: T2 sagittal, B: T2 axial images (the location and orientation of this slice is shown as the yellow line in A).
The *yellow arrowheads* indicate the location of compression of the nerve root en passant (the S1 nerve root).
Note that compared to the normal high density of the L2–3 and L3–4 discs, the lower density of the L4–5 and L5–S1 discs are consistent with disc degeneration. The L5-S1 disc has also lost some height.

74.7.5 Myelography

With water-soluble intrathecal contrast introduced via lumbar puncture, sensitivity (62–100%) and specificity (83–94%)[32,33,34,35] are similar to CT for detection of HLD. Usually combined with post-myelographic CT scan (myelogram/CT), which increases the sensitivity and especially the specificity.[36] A herniated disc in the large space between the thecal sac and posterior border of vertebral bodies at L5–1 (insensitive space) may not be seen on myelography alone (CT or MRI are usually better at demonstrating this).

Advantages:

1. evaluates cauda equina better than noncontrast CT
2. provides “functional” information about degree of stenosis (a high-degree block will allow flow of dye only after certain position changes)
3. when combined with CT, may demonstrate some anatomy obscured by metal artifact on MRI in patients with prior instrumentation

Disadvantages:

1. may miss pathology outside of the dura (including far laterally herniated disc); sensitivity is improved with post-myelographic CT
2. invasive
   a) drugs e.g., warfarin must be stopped, and sometimes bridged to heparin
   b) with occasional side effects (post LP H/A, N/V, rare seizures)
3. iodine-allergic patients
   a) requires iodine allergy prep
   b) may still be risky (especially in severely iodine-allergic patients)

Findings:

HLD produces extradural filling defect at the level of the intervertebral disc. Massive disc herniation or severe lumbar stenosis may produce a total or near-total block. In some cases of HLD, the finding may be very subtle and may consist of a cut-off of the filling (with contrast) of the nerve root sleeve (compared to normal nerve(s) on contralateral side or at other levels). Another subtle finding may be a "dual shadow" on lateral view.

74.7.6 Bone scan for low back problems

Description: injection of a radiolabeled compound (usually technetium-99m) that is taken up by metabolically active bone. A gamma camera localizes regions of uptake. Total radiation dose is ≈ to a set of lumbar spine X-rays.[1] Contraindicated during pregnancy. Breast feeding must be briefly suspended following a bone scan due to presence of radiotracer in the breast milk.

A moderately sensitive test which may be used in evaluating low back pain when spinal tumor,[37] infection,[38] or occult fracture is suspected from "red flags" (see ▶ Table 74.4) on history or examination, or results of lab tests or plain X-rays. Not very specific, but may locate occult lesions and help differentiate these conditions from degenerative changes. A positive bone scan suggesting one of these conditions usually must be confirmed by other diagnostic tests or procedures (no studies have compared bone scans to CT or MRI).

Low yield in patients with longstanding low back problems and normal plain X-rays and laboratory tests (especially ESR or CRP).[37]

SPECT scans may provide additional information to a bone scan.

74.7.7 Discography

General information

Injection of water-soluble contrast agent directly into the nucleus pulposus of the intervertebral disc being studied by percutaneous needle access through Kambin's triangle (▶ Fig. 74.3) in an awake patient. Results of the test depend on volume of dye accepted into the disc, the pressure needed to inject the dye, the configuration of the dye (including leakage from the confines of the disc space) on radiographic imaging (plain X-rays produce the so-called "discogram"; CT scan is often also utilized following the injection), and reproduction of the patient's pain on injection. Some of the basis for performing a discogram is to identify levels that may produce "discogenic pain" or "painful disc syndrome" (p. 1235), a controversial point. When the pain produced mimics the patient's presenting pain, the pain is said to be "concordant."

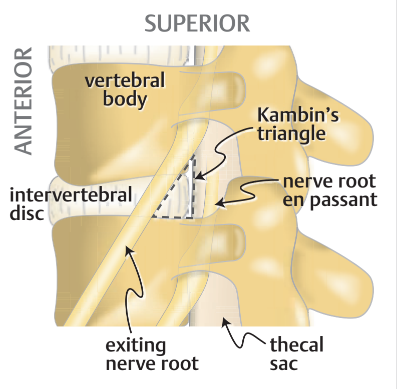

Fig. 74.3 Kambin's triangle.
Image: lateral diagramatic view of Kambin's triangle (*heavy broken line*), a right triangle bounded at the hypotenuse by the exiting nerve root, inferiorly by the superior endplate of the inferior vertebral body, and medially by the thecal sac.

Critique

Invasive. Interpretation is equivocal, and complications may occur (disc space infection, disc herniation, and significant radiation exposure with CT-discography). May be abnormal in asymptomatic patients[21,22] (as any of the above tests may be), but the false-positive rate is almost certainly not as high as reported in an older study (pain provoked in 100% of injections[21]).[39] See **Practice guideline: MRI and discography for patient selection for lumbar fusion** (p. 1231) for recommendations.

74.7.8 Thermography for low back problems

✖ Not recommended.[1] Did not accurately predict absence or presence of nerve root compression seen at surgery,[40] and may be positive in a significant percentage of asymptomatic patients.[41]

74.8 Electrodiagnostics for low back problems

If the diagnosis of radiculopathy seems likely on clinical grounds, electrophysiologic testing is not recommended.[1]

1. needle EMG (p. 255): can assess acute and chronic nerve root dysfunction, myelopathy and myopathy, and may be useful for patients with suspicion of other conditions (e.g., neuropathy) or when a reliable strength exam is not possible. Reduced recruitment may be seen within the first several days of onset; however, spontaneous activity (p. 255) takes 10–21 days to develop (∴ less helpful in the first ≈ 3 weeks). Also, not usually helpful with normal muscle strength exam. Accuracy is highly operator-dependent and improves with knowledge about imaging studies and clinical information.[42] See findings in radiculopathy (p. 256).
2. H-reflex (p. 255): measures sensory conduction through nerve roots. Use is limited to assessing S1 radiculopathy.[43] Correlates with Achilles reflex.
3. SSEPs (p. 250): assesses afferent fibers which travel in peripheral nerve and the posterior column of the spinal cord. May be abnormal in conditions affecting the dorsal columns with impaired joint position and proprioception (e.g., cervical spondylotic spinal myelopathy)
4. nerve conduction studies (including NCVs): helps identify acute and chronic entrapment neuropathies that may mimic radiculopathy
5. ✖ not recommended for assessing acute low back problems[1]
   a) F-wave response (p. 255): measures motor conduction through nerve roots, used to assess proximal neuropathies
   b) surface EMG: assesses acute and chronic recruitment patterns during static or dynamic tasks using surface (instead of needle) electrodes

74.9 Psychosocial factors

Although some patients with chronic LPB (> 3 months duration) may have started off with a diagnosable condition, psychological and socioeconomic factors (such as depression, secondary gain…) may come to play a significant role in perpetuating or amplifying pain. Psychological factors, especially elevated hysteria or hypochondriasis scales on the Minnesota Multiphasic Personality Inventory (MMPI) were found to be a better predictor of outcome than findings on radiographic imaging in one study.[42] A screening scale of 5 factors has been proposed[44] (positive findings in any 3 suggests psychological distress):

1. These items are potentially reliable[45]:
   a) pain on simulated axial loading: press on top of head
   b) inconsistent performance: e.g., difficulty tolerating straight leg raising (SLR) while supine, but no difficulty when sitting
   c) overreaction during the physical exam
2. These items may not be reliable[45]:
   a) inappropriate tenderness that is superficial or widespread
   b) motor or sensory abnormalities not corresponding to anatomic boundaries (e.g., for sensation: dermatomes, peripheral nerve distribution…)

However, the usefulness of this information is limited, and no effective interventions have been identified to address these factors. Therefore the Agency for Health Care Policy and Research (AHCPR) panel was unable to recommend specific assessment tools or interventions.[1]

74.10 Treatment

74.10.1 General information

An initial period of nonsurgical management (see below) is indicated except in the following circumstances where urgent surgery is indicated:

Situations where conservative treatment is not indicated:

- symptoms of cauda equina syndrome: urinary retention, saddle anesthesia... (p. 1254)
- progressive neurologic deficit, or profound motor weakness

- a relative indication for proceeding to urgent surgery without conservative management is severe pain that cannot be sufficiently controlled with adequate pain medication (rare)

If specific diagnoses such as herniated intervertebral lumbar disc or symptomatic lumbar stenosis are made, surgical treatment for these conditions may be considered if the patient fails to improve satisfactorily. In cases where no specific diagnosis can be made, management consists of conservative treatment and following the patient to rule out the possible development of symptoms suggestive of a more serious diagnosis that may not have initially been evident.

74.10.2 "Conservative" treatment

This term has regrettably come to be used for non-surgical management. With minor modification, similar approaches can be used for mechanical low back pain, as well as for acute radiculopathy from disc herniation.

Recommendations (based on AHCPR findings[1] in the absence of "red flags"; note: some key literature citations are given here, primarily those from the better studies that support the AHCPR panel recommendations. However, refer to Bigos et al[1] for full analysis and list of references):

1. activity modifications: no studies were found that met the panel's review criteria for adequate evidence. However, the following information was felt to be useful:
    a) bed rest: for 2–3 days maximum
        - the theoretical objective is to reduce symptoms by reducing pressure on the nerve roots and/or intradiscal pressures, which is lowest in the supine semi-Fowler position,[46] and also to reduce movements which are experienced as painful by the patient
        - deactivation from prolonged bed rest (> 4 days) appears to be worse for patients (producing weakness, stiffness, and increased pain) than a gradual return to normal activities[47]
        - recommendations: the majority of patients with low back problems will not require bed rest. Bed rest for 2–4 days may be an option for those with severe initial radicular symptoms; however, this may be no better than watchful waiting[48] and may be harmful[49]
    b) activity modification
        - the goal is to achieve a tolerable level of discomfort while continuing sufficient physical activity to minimize disruption of daily activities
        - risk factors: although there is not agreement on their exact role, the following were identified as having an increased incidence of low back problems. Jobs requiring heavy or repetitive lifting, total body vibration (from vehicles or industrial machinery), asymmetric postures, or postures sustained for long periods (including prolonged sitting)
        - recommendations: temporarily limit heavy lifting, prolonged sitting, and bending or twisting of the back. Establish activity goals to help focus attention on expected return to full functional status
    c) exercise (may be part of a *physical therapy* program):
        - during the 1st month of symptoms, low-stress aerobic exercise can minimize debility due to inactivity. In the first 2 weeks, utilize exercises that minimally stress the back: walking, bicycling, or swimming
        - conditioning exercises for trunk muscles (especially back extensors, and possibly abdominal muscles) are helpful if symptoms persist (during the first 2 weeks, these exercises may aggravate symptoms)
        - there is no evidence to support stretching of back muscles, or to recommend back-specific exercise machines over traditional exercise
        - recommended exercise quotas that are gradually escalated results in better outcome than having patients simply stop when pain occurs[50]
2. analgesics
    a) for the initial short-term period, acetaminophen (APAP) or NSAIDs (p. 144) may be used. In one study[51] of acute LBP, NSAIDs did not add any benefit to APAP + standard education (see below)
    b) stronger analgesics—mostly opioids (p. 146)—may be required for severe pain, primarily for severe radicular pain. For non-specific back pain, there was no earlier return to full activity than with NSAIDs or APAP.[1] Opioids should not be used > 2–3 weeks, at which time NSAIDs should be instituted unless contraindicated
3. muscle relaxants
    a) the therapeutic objective is to reduce pain by relieving muscle spasm. However, muscle spasms have not been proven to cause pain, and the most commonly used muscle relaxants have no peripheral effect on muscle spasm

   b) probably more effective than placebo, but have not been shown to be more effective than NSAIDs, and their use in combination with NSAIDs has not been shown to be more effective than use of NSAIDs alone
   c) potential for side effects: drowsiness (in up to 30%). Most manufacturers recommend use for < 2–3 weeks. Agents such as chlorzoxazone (Parafon Forte® and others) may be associated with risk of serious and potentially fatal hepatotoxicity[52]
4. education (may be provided as part of a *physical therapy* program):
   a) explanation of the condition to the patient[53] in understandable terms, and positive reassurance that the condition will almost certainly subside[54] have been shown to be more effective than many other forms of treatment
   b) proper posture, sleeping positions, lifting techniques… should be conveyed to the patient. Formal "back school" seems to be marginally effective.[55] There may be some early benefit, but long-term efficacy could not be shown.[56] The quality and expense of such programs varies widely[1]
5. spinal manipulation therapy (SMT): defined as manual therapy in which loads are applied to the spine using long or short lever methods with the selected joint being taken to its end range of voluntary motion, followed by application of an impulse loading (may be part of a *physical therapy* program)
   a) may be helpful for patients with acute low back problems without radiculopathy when used in the first month of symptoms (efficacy after 1 month is unproven) for a period not to exceed 1 month. One study[51] found no added benefit to APA + standard education
   b) there is insufficient evidence to recommend SMT in the presence of radiculopathy
   c) SMT should not be used in the face of severe or progressive neurologic deficit until serious conditions have been ruled out
   d) ✖ reports of arterial dissection: especially vertebral artery (p. 1579) and stroke, myelopathy & subdural hematoma with *cervical* SMT and cauda equina syndrome with lumbar SMT[57,58,59] and the uncertainty of benefits have led to the questioning of the use of SMT[57] (especially cervical)
6. epidural injections:
   a) epidural (cortico)steroid injections (ESI): there is no evidence that this is effective in treating acute radiculopathy.[60] Most studies that show benefit are retrospective and noncontrolled. Prospective studies yield varied results.[61] Some improvement at 3 & 6 weeks may occur (but no functional benefit, and no change in the need for surgery), with no benefit at 3 months.[62] The response in chronic back pain is poor in comparison to acute pain. ESI may be an option for *short-term* relief of radicular pain when control on oral medications is inadequate or for patients who are not surgical candidates
   b) there is no evidence to support the use of epidural injections of steroids, local anesthetics, and/or opioids for LBP without radiculopathy
   c) reports on efficacy with conditions such as lumbar spinal stenosis are conflicting,[61] relief is almost uniformly temporary (4–6 weeks with initial injection, shorter times with subsequent ones)

✖ *Not* recommended by the AHCPR panel[1] for treatment of acute low back problems in the absence of "red flags" (▶ Table 74.4):

1. medications
   a) oral steroids: no difference was found at 1 week and 1 year after randomization to receive 1 week therapy with oral dexamethasone or placebo[63]
   b) colchicine: conflicting evidence shows either some[64] or no[65] therapeutic benefit. Side effects of N/V and diarrhea were common[1]
   c) antidepressant medications: most studies of these medications were for chronic back pain. Some methodologically flawed studies failed to show benefits when compared to placebo for chronic (not acute) LBP[66]
2. physical treatments
   a) TENS (transcutaneous electrical nerve stimulation): *not* statistically significantly better than placebo, and added no benefit to exercise alone[67]
   b) traction (including pelvic traction): not demonstrated to be effective.[68] One possible explanation for lack of benefit is that due to the sizable paraspinal muscles and ligaments (as compared to the cervical spine) the amount of weight required to distract the intervertebral disc space is approximately ≥ 2/3 of the patient's body weight, which is painful and/or pulls the patient to the foot of the bed
   c) physical agents and modalities: including heat (including diathermy), ice, ultrasound. Benefit is insufficiently proven to justify their cost; however, self-administered home programs for

application of heat or cold may be considered. Ultrasound and diathermy should not be used in pregnancy

  d) lumbar corsets and support belts: not proven beneficial for acute back problems. Prophylactic use has been advocated to reduce time lost from work by individuals doing frequent lifting as part of their job, but this is controversial[69]
  e) biofeedback: has not been studied for acute back problems. Primarily advocated for chronic LBP, where effectiveness is controversial[70]

3. injection therapy
  a) trigger point and ligamentous injections: the theory that trigger points cause or perpetuate LBP is controversial and disputed by many experts. Injections of local anesthetic are of equivocal efficacy (saline may be as effective[71]) and are mildly invasive
  b) (zygapophyseal) facet joint injections: theoretical basis is that there exists a "facet syndrome" producing LBP which is aggravated by spine extension, with no nerve root tension signs (p. 1251). No studies have adequately investigated injections for pain < 3 months duration. For chronic LBP, neither the agent nor the location (intrafacet or pericapsular) made a significant difference in outcomes[72,73]
  c) epidural injections in the absence of radiculopathy: see above
  d) acupuncture: no studies were found that evaluated the use in acute back problems. All randomized clinical trials found were for patients with chronic LBP, and even the best studies were felt to be mediocre and contradictory. Meta-analysis found acupuncture was more effective in relieving chronic LBP than sham or no treatment,[74] but there was no comparison to other therapies

Practice guideline: Injection therapy for low back pain

Therapeutic recommendations

Level III[75]: lumbar epidural injections or trigger point injections are not recommended for long-term relief of chronic LBP. These techniques or facet injections may be used to provide temporary relief in select patients

Diagnostic recommendations

Level III[75]: lumbar facet injections
- may predict the response to radiofrequency facet ablation
- ✖ not recommended as a diagnostic tool to predict the response to lumbar fusion

74.10.3 Surgical treatment

Indications for surgery for herniated lumbar disc

See the section on **herniated lumbar discs** (p. 1256).

Indications for fusion for chronic LBP without stenosis or spondylolisthesis

Very controversial.

Practice guideline: Lumbar fusion for LBP without stenosis or spondylolisthesis

Level I[76]: lumbar fusion is recommended for carefully selected patients with disabling LBP due to one- or two-level degenerative disease without stenosis or spondylolisthesis (in the primary quoted study[77] patients had chronic LBP for ≥ 2 years and had radiologic evidence of disc degeneration at L4–5, L5–1, or both, and had failed best medical management).

Level III[76,78]: an intensive course of PT and cognitive therapy is recommended as an option for patients with LBP in whom conventional medical management has failed.

Practice guideline: Choice of fusion technique

Level II[79]: for ALIF or ALIF + instrumentation, the addition of a posterolateral fusion is not recommended (the demonstrated benefit does not outweigh the additional time and blood loss involved).

Level III[79]:

- either a posterolateral fusion or an interbody fusion (PLIF, TLIF, or ALIF) are options for patients with LBP due to DDD at 1 or 2 levels
- an interbody graft is an option to improve fusion rates and functional outcome (caution: the improvement in fusion rate and outcome is marginal, and interbody fusion is associated with an increased complication rate, especially with combined approaches, e.g., 360° fusion)

✖ the use of multiple approaches (anterior + posterior) is not recommended as a routine option for LBP without deformity

Surgical treatment options

The type of surgical procedure chosen is tailored to the specific condition identified. Examples are shown in ▶ Table 74.5. Discussion of some options is also provided below.

Table 74.5 Surgical options for low back problems

Condition	Surgical treatment options
“routine” HLD or initial recurrence of HLD	• standard discectomy and microdiscectomy are of similar efficacy • ✖ intradiscal procedures: nucleotome, laser disc decompression are not recommended (p. 1257)
foraminal or far lateral HLD	• partial or total facetectomy (p. 1265) • extracanal approach (p. 1265) • endoscopic techniques
lumbar spinal stenosis	• simple decompressive laminectomy • laminectomy plus fusion: may be indicated for patients with degenerative spondylolisthesis, stenosis and radiculopathy, adult degenerative scoliosis (ADS), or instability

Lumbar spinal fusion

Although there is no consensus on the indications,[80] lumbar spinal fusion (LSF) is most widely accepted as part of treatment for fracture-dislocation or instability resulting from tumor or infection.

For degenerative spine disease, practice parameters have been developed and are included herein. Pain associated with Modic type 1 changes (bone edema, see ▶ Table 81.5) may respond to stabilization procedures, the other Modic types do not exhibit this association. A substantial number of patients with herniated lumbar disc and radiculopathy who also have LBP will have relief of LBP.[81,82,83]

Practice guideline: Lumbar fusion for disc herniation

Level III[84]:

1. lumbar fusion is *not* routinely recommended following disc excision in patients with HLD or 1st time recurrent HLD causing radiculopathy
2. lumbar fusion is a potential adjunct to disc excision in cases of an HLD or recurrent HLD:
   a) with evidence of preoperative lumbar spinal deformity or instability
   b) in patients with chronic axial LBP associated with radiculopathy

Instrumentation as an adjunct to fusion

Practice guideline: Pedicle screw fixation

Level III[85]: pedicle screw fixation is recommended as a treatment option for patients with LBP treated with posterolateral fusion who are at high risk for fusion failure (routine use of pedicle screws is discouraged because of conflicting evidence of benefit, together with considerable evidence of increased cost and complications).

The use of instrumentation increases the fusion rate.[86] Hardware used in the absence of fusion will eventually fatigue (with one or more of the following: breakage of rods and/or screws, screw pullout, or spine fracture). Therefore, instrumentation must be viewed as a temporary internal stabilizing measure while awaiting the fusion process to complete.

74.11 Chronic low back pain

Rarely can an anatomic diagnosis be made in patients with chronic LBP ≥ 3 months duration.[87] Also, see Psychosocial factors (p. 1236). Patients with chronic pain syndromes (CPS) refer to their problems with affective or emotional terms with a higher frequency than those with acute pain.[88] The amount of time that a patient has been out of work due to low back problems is related to the chances of the patient getting back to work as shown in ▶ Table 74.6.

Table 74.6 Chances of patients going back to work

Time out of work	Chances of getting back to work
< 6 mos	50%
1 yr	20%
2 yrs	< 5%

74.12 Coccydynia

74.12.1 General information

Pain and tenderness around the coccyx. A symptom, not a diagnosis. Typically, discomfort is experienced on sitting or on rising from sitting. More common in females, possibly due to a more prominent coccyx. The condition is unusual enough in males that in the absence of local trauma, strong consideration should be given to an underlying condition.

74.12.2 Etiologies

For differential diagnosis, see Acute low back pain (p. 1706). Better accepted etiologies include[89]:

1. local trauma (may be associated with fracture or dislocation):
   a) 25% of patients give a history of a fall
   b) 12% had repetitive trauma (rowing machine, prolonged bicycle riding…)
   c) 12% started with parturition
   d) 5% started following a surgical procedure (half of which were in the lithotomy position)
2. idiopathic: excluding traumatic cases, no etiology can be identified in most cases
3. neoplasms
   a) chordoma
   b) giant cell tumor
   c) intradural schwannoma
   d) perineural cyst
   e) intraosseous lipoma
   f) carcinoma of the rectum
   g) sacral hemangioma[90]
   h) pelvic metastases (e.g., from prostate cancer)
4. prostatitis

Controversial etiologies include[89,91]:

1. local pressure over a prominent coccyx
2. referred pain:
   a) spinal disease
      - herniated lumbosacral disc
      - cauda equina syndrome
      - arachnoiditis
   b) pelvic/visceral disease
      - pelvic inflammatory disease (PID)
      - perirectal abscess
      - perirectal fistula
      - pilonidal cyst
3. inflammation of the various ligaments attached to the coccyx
4. neurosis or frank hysteria

Histological evaluation of the coccyx has not helped delineate the cause, even though avascular necrosis has been suggested.[92]

74.12.3 Evaluation

MRI: effective for detecting soft tissue masses, including presacral masses.

CT scan: no characteristic finding in coccydynia findings. Very sensitive for detecting bony pathology (fracture, destructive lesion…).

Sacrococcygeal films are often performed to rule out a bony destructive lesion. Often, the question of a fracture will be raised, and many times cannot be definitely ruled in or out based on this study. There may or may not be any significance to such a fracture.

Nuclear bone scans were not helpful in 50 patients with coccydynia.[89]

74.12.4 Treatment

Numerous treatments have been proposed, and some are offered here for historical purposes[89] (and to dissuade casual attempts to effect a "new" cure that in reality has already been tried):

1. plaster jackets
2. hot baths (sitz baths), heating pads
3. massage therapy
4. XRT
5. psychotherapy

Most cases resolve within ≈ 3 months of conservative management consisting of NSAIDs, mild analgesics, and measures to reduce pressure on the coccyx (e.g., a rubber ring ("doughnut") sitting cushion, lumbar supports to maintain sitting lumbar lordosis to shift weight from coccyx to posterior thighs).[93]

Management recommendations for refractory cases[89,93]:

1. local injection: 60% respond to corticosteroid + local anesthetic (40 mg Depo-Medrol® in 10 cc of 0.25% bupivacaine). Recommended as initial treatment; response should be achieved by 2 injections
2. manipulation of the coccyx: usually under general anesthesia. ≈ 85% successful when combined with local injection
3. ± physiotherapy (diathermy & ultrasound): found to be of benefit only in ≈ 16% (may be more effective with the addition of gentle manipulation of the coccyx *without* general anesthesia[94])
4. caudal epidural steroid injection
5. blockade or neurolysis (with chemicals or by cryoablation[95]) of the ganglion impar (AKA ganglion of Walther, the lowest ganglion of the paired paravertebral sympathetic chain, located just anterior to the sacrococcygeal junction): some success has been described with this technique (traditionally used for intractable sympathetic perineal pain of neoplastic etiology[96])
6. neurolytic techniques directed to S4, S5, and coccygeal nerves
7. coccygectomy (surgical removal of the mobile portion of the coccyx, followed by smoothening of the residual bony prominence on the sacrum): was required in ≈ 20% of patients in one series,[89] with a reported success rate of 90%. However, many practitioners do not view this as a highly effective treatment and feel that great restraint should be used in considering this form of therapy

74.12.5 Recurrence

Occurs in ≈ 20% of conservatively treated cases, usually within the first year. Repeat therapy was often successful in providing permanent relief. More aggressive treatment may be considered for refractory cases.

74.13 Failed back surgery syndrome

74.13.1 General information

Definition: failure to satisfactorily improve low back pain or radiculopathy following back surgery. These patients often require analgesics and are unable to return to work. The failure rate for lumbar discectomy to provide satisfactory long-term pain relief is ≈ 8–25%.[97] Pending legal or worker's compensation claims were the most frequent deterrents to a good outcome.[98]

74.13.2 Etiologies

Factors that may cause or contribute to the failed back syndrome:

1. incorrect initial diagnosis
   a) inadequate pre-op imaging
   b) clinical findings not correlated with abnormality demonstrated on imaging
   c) other causes of symptoms (sometimes in the presence of what was considered to be an appropriate lesion on imaging studies which may have been asymptomatic): e.g., trochanteric bursitis, diabetic amyotrophy…
2. continued nerve root or cauda equina compression caused by:
   a) residual compression (retained disc material, osteophytes…)
   b) recurrent pathology at same level: disc reherniation at the same level, usually have pain-free interval > 6 mos post-op (p. 1267); or restenosis (over many years[99]—was more common with midline fusions)
   c) adjacent level pathology: disc herniation or stenosis[99]
   d) compression of nerve root by peridural scar (granulation) tissue (see below)
   e) pseudomeningocele
   f) epidural hematoma
   g) conjoined nerve roots with compression at another level or in atypical location
   h) segmental instability: 3 patterns,[100] 1) lateral rotational instability, 2) post-op spondylolisthesis, 3) post-op scoliosis
3. permanent nerve root injury from the original disc herniation or from surgery, includes deafferentation pain which is usually constant and burning or ice cold
4. adhesive arachnoiditis: responsible for 6–16% of persistent symptoms in post-op patients[101] (see below)
5. discitis (p. 390): usually produces exquisite back pain 2–4 weeks post-op
6. spondylosis
7. other causes of back pain unrelated to the original condition: paraspinal muscle spasm, myofascial syndrome… Look for trigger points, evidence of spasm
8. post-op reflex sympathetic dystrophy (RSD) (p. 1259)
9. "non-anatomic factors": poor patient motivation, secondary gains, drug addiction, psychological problems (p. 1258)…

74.13.3 Arachnoiditis (AKA adhesive arachnoiditis)

General information

Inflammatory condition of the lumbar nerve roots. Actually a misnomer, since adhesive arachnoiditis is really an inflammatory process or fibrosis that involves all three meningeal layers (pia, arachnoid, and dura).

Etiologies/risk factors

Many putative "risk factors" have been described for the development of arachnoiditis, including[102]:

1. spinal anesthesia: either due to the anesthetic agents or to detergent contaminants on the syringes used for same
2. spinal meningitis: pyogenic, syphilitic, tuberculous

3. neoplasms
4. myelographic contrast agents: less common with currently available nonionic water-soluble contrast agents
5. trauma:
   a) post-surgical: especially after multiple operations
   b) external trauma
6. hemorrhage
7. idiopathic

Radiographic findings in arachnoiditis

NB: Radiographic evidence of arachnoiditis may also be found in *asymptomatic* patients.[102] Arachnoiditis must be differentiated from tumor: the central adhesive type (see below) may resemble CSF seeding of tumor, and myelographic block may mimic intrathecal tumor.

MRI

3 patterns on MRI[103,104]:

1. central adhesion (clumping) of the nerve roots into 1 or 2 central "cords"
2. "empty thecal sac" pattern: (▶ Fig. 74.4) roots adhere to meninges around periphery, giving the appearance of a thecal sac containing only CSF
3. thecal sac filled with inflammatory tissue, no CSF signal. Corresponds with myelographic block and *candle-dripping* appearance

Enhancement: acute arachnoiditis may enhance. Chronic arachnoiditis usually does not enhance with gadolinium as much as e.g., tumor.

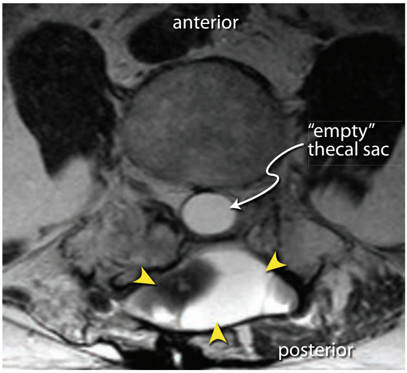

Fig. 74.4 "Empty thecal sac" appearance of arachnoiditis.
Axial T2 MRI through L4 in patient with adhesive arachnoiditis demonstrating nerve roots that are plastered against the posterior wall of the thecal sac and are thus not visible, giving the appearance of an empty thecal sac (bright oval).
The patient also has a pseudomeningocele (*yellow arrowheads*).

Myelogram

May demonstrate complete block, or clumping of nerve roots. One of many myelographic classification systems[105] for arachnoiditis is shown in ▶ Table 74.7.

Table 74.7 Myelographic classification of arachnoiditis

Type	Description
1	unilateral focal filling defect centered on the nerve root sleeve adjacent to disc space
2	circumferential constriction around thecal sac
3	complete obstruction with "stalactites" or "candle guttering," "candle-dripping," or "paint-brush" filling defects
4	infundibular cul-de-sac with loss of radicular striations

74.13.4 Peridural scar

General information

Although peridural scar tissue is frequently blamed for causing recurrent symptoms,[106,107] there has been no proof of correlation between the two.[108] Peridural fibrosis is an inevitable sequelae to lumbar disc surgery just as post-op fibrosis is a consequence of any surgical procedure. Even patients who are relieved of their pain following discectomy develop some scar tissue post-op.[109] Although it has been shown that if a patient has recurrent radicular pain following a lumbar discectomy there is a 70% chance that extensive peridural scar will be found on MRI,[108] this study also showed that on post-op MRIs at 6 months, 43% of patients will have extensive scar, but 84% of the time this will be *asymptomatic*.[110] Thus, one must use clinical grounds to determine if a patient with extensive scar on MRI is in the 16% minority of patients with radicular symptoms attributable to scar.[110]

See a discussion of measures to reduce peridural scarring (p. 1258).

Radiologic evaluation

General information

Patients with only persistent low back or hip pain without a strong radicular component, with a neurologic exam that is normal or unchanged from pre-op, should be treated symptomatically. Patients with signs or symptoms of recurrent radiculopathy (positive SLR is a sensitive test for nerve root compression), especially if these follow a period of apparent recovery, should undergo further evaluation.

It is critical to differentiate residual/recurrent disc herniation from scar tissue and adhesive arachnoiditis as surgical treatment has generally poor results with the latter two (see below).

MRI without and with IV gadolinium

Diagnostic *test of choice*. The best exam for detecting residual or recurrent disc herniation, and to reliably differentiate disc from scar tissue. Pre-contrast studies with T1WI and T2WI yield an accuracy of ≈ 83%, comparable to IV-enhanced CT.[111,112] With the addition of gadolinium, using the protocol below yields 100% sensitivity, 71% specificity, and 89% accuracy.[113] May also detect adhesive arachnoiditis (see above). As scar becomes more fibrotic and calcified with time, the differential enhancement with respect to disc material attenuates and may become undetectable at some point, ≈ 1–2 years post-op[112] (some scar continues to enhance for > 20 yrs).

Recommended MRI protocol

See reference.[113]

Get pre-contrast T1WI and T2WI. Give 0.1 mmol/kg gadolinium IV. Obtain T1WI images within 10 minutes (early post-contrast). No benefit from post-contrast T2WI.

Findings on unenhanced MRI

Signal from an HLD becomes more intense as the sequence is varied from T1WI → T2WI, whereas scar tissue becomes less intense with this transition. Indirect signs (also applicable to CT):

1. mass effect: a nerve root is displaced away from disc material, whereas it may be retracted toward scar tissue by adherence to it
2. location: disc material tends to be in contiguity with the disc interspace (best seen on sagittal MRI)

Findings on enhanced MRI

On early (≤ 10 mins post-contrast) T1WI images: scar enhances inhomogeneously, whereas disc does not enhance at all. A nonenhancing central area surrounded by irregular enhancing material probably represents disc wrapped in scar. Venous plexus also enhances, and may be more pronounced when it is distorted by disc material, but the morphology is easily differentiated from scar tissue in these cases.

On late (> 30 mins post-contrast) T1WI: scar enhances homogeneously, disc had variable or no enhancement. Normal nerve roots do not enhance even on late images.

CT scan without and with IV (iodinated) contrast

Unenhanced CT scan density measurements are unreliable in the postoperative back.[114] Enhanced CT is only fairly good in differentiating scar (enhancing) from disc (unenhancing with possible rim enhancement). Accuracy is about equal to *unenhanced* MRI.

Myelography, with post-myelographic CT

Postoperative myelographic criteria alone are unreliable for distinguishing disc material from scar.[102,115] With the addition of CT scan, neural compression is clearly demonstrated, but scar still cannot be reliably distinguished from disc.

Myelography (especially with post-myelographic CT) is very capable of demonstrating arachnoiditis[115] (see above).

Plain LS X-rays

Generally helpful only in cases of instability, malalignment, or spondylosis.[115] Flexion/extension views are most helpful when trying to demonstrate instability.

74.13.5 Treatment of failed back surgery syndrome

Postoperative discitis

For treatment of intervertebral disc-space infection, see Discitis (p. 390).

Symptomatic treatment

Recommended for patients who do not have radicular signs and symptoms, or for most patients demonstrated to have scar tissue or adhesive arachnoiditis on imaging. As in other cases of non-specific LBP, treatment includes: short-term bed rest, analgesics (non-narcotic in most cases), anti-inflammatory medication (non-steroidal, and occasionally a short course of steroids), and physical therapy.

Surgery

Generally reserved for those with recurrent or residual disc herniation, segmental instability, or patients with a pseudomeningocele. Patients with post-op spinal instability should be considered for spinal fusion (p. 1240).[100]

In most series with sufficient follow-up, success rates after reoperation are lower in patients with only epidural scar (as low as 1%) compared to those patients with disc and scar (still only ≈ 37%).[97] An overall success rate (> 50% pain relief for > 2 yrs) of ≈ 34% was seen in one series,[107] with better results in patients who were young and female, with good results following previous surgery, a small number of previous operations, employment prior to surgery, predominantly radicular (cf axial) pain, and absence of scar requiring lysis.

In addition to the absence of disc material, factors associated with poor outcome were: sensory loss involving more than one dermatome, and patients with past or pending compensation claims.[97,116]

Arachnoiditis:

Surgery for carefully selected patients with arachnoiditis (those with mild radiographic involvement (Types 1 & 2 in ▶ Table 74.7), and < 3 previous back operations)[105] has met with moderate success (although in this series, no patient returned to work). Approximate success rate in other series[117,118]: 50% failure, 20% able to work but with symptoms, 10–19% with no symptoms. Surgery consists of removal of extradural scar enveloping the thecal sac, removing any herniated disc fragments, and performing foraminotomies when indicated. Intradural lysis of adhesions is *not* indicated since no means for preventing reformation of scar has been identified.[118]

75 Lumbar Disc Herniation and Radiculopathy

75.1 General information

Key concepts

- radiculopathy: pain and/or subjective sensory changes (numbness, tingling…) in the distribution of a nerve root dermatome, possibly accompanied by weakness and reflex changes of muscles innervated by that nerve root
- typical disc herniation → radiculopathy in the nerve exiting at the level below
- massive disc herniations can → cauda equina syndrome (a medical emergency). Typical symptoms: saddle anesthesia, urinary retention, LE weakness (p. 1254).
- most patients do as well with conservative treatment as with surgery, ∴ initial nonsurgical (conservative) treatment should be attempted for the vast majority
- surgery indications: cauda equina syndrome, progressive symptoms or neurologic deficits despite conservative treatment, or severe radicular pain > ≈ 6 weeks

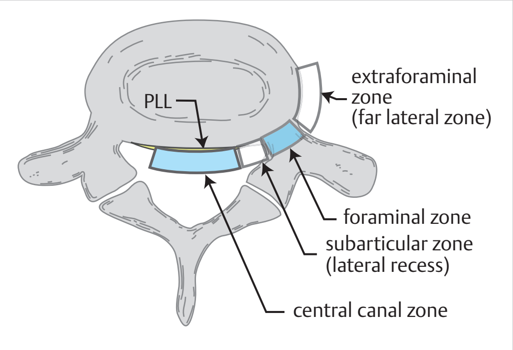
75.2 Pathophysiology

Intervertebral discs may undergo degenerative changes (p. 1327); see ▶ Table 74.1 for description: this includes desiccation and fibrosis, which further leads to fissuring and tearing, which in turn increases the risk of herniation of disc material outside the normal confines of the disc space.

75.3 Herniation zones

75.3.1 General information

Lumbar disc herniations typically occur in one of several zones illustrated in ▶ Fig. 75.1.



PLL
extraforaminal zone (far lateral zone)
foraminal zone
subarticular zone (lateral recess)
central canal zone

Fig. 75.1 Zones of lumbar disc herniation. Abbreviation: PLL = posterior longitudinal ligament.

75.3.2 Central and paramedial disc herniations

The posterior longitudinal ligament is strongest in the midline, and the posterolateral annulus may bear a disproportionate portion of the load exerted by the weight from above. This may explain why most posteriorly herniated lumbar discs (HLD) occur slightly off to one side (paramedian) within the central canal zone or in the subarticular zone (▶ Fig. 75.1). In the lumbar spine this characteristically compresses the nerve root en passant (that is, the nerve in the lateral recess just before it exits through the neural foramen of the level *below*; e.g., at L4–5 this would typically involve the L5 nerve root).

75.3.3 Extreme lateral disc herniation

Disc herniations in the foraminal zone or extraforaminal zone are often considered extreme lateral and often involve the nerve root *exiting* at that level (p. 1263).

75.4 Other disc herniation variants

1. intravertebral disc herniation (p. 1266): AKA Schmorl's node.
2. intradural disc herniation (p. 1266)
3. limbus fracture: traumatic separation of a segment of bone from the edge of the vertebral ring apophysis at the site of anular attachment. May accompany HLD

75.5 Clinical findings with hernaited lumbar disc

75.5.1 Characteristic findings on the history

- symptoms may start off with back pain, which after days or weeks gradually or sometimes suddenly yields to radicular pain often with reduction of the back pain
- precipitating factors: various factors are often blamed, but are rarely identified[1] with certainty
- pain relief upon flexing the knee and thigh (e.g., lying supine with a pillow under the knees)
- patients generally avoid excessive movements; however, remaining in any one position (sitting, standing, or lying) too long may also exacerbate the pain, sometimes necessitating position changes at intervals that range from every few minutes to 10–20 minutes. This is distinct from constant writhing in pain e.g., with ureteral obstruction
- "cough effect": ↑ pain with coughing, sneezing, or straining at the stool. Occurred in 87% of patients with HLD in one series[2]
- bladder symptoms: the incidence of voiding dysfunction is 1–18%.[3 (p 966)] Most common: difficulty voiding, straining, or urinary retention. Reduced bladder sensation may be the earliest finding. The possible causes of this are sensory loss, or incomplete interruption of the preganglionic parasympathetic fibers. Later it is not unusual to see "irritative" symptoms including urinary urgency, frequency (including nocturia), increased post-void residual. Less common: enuresis, and dribbling incontinence[4]; NB: urinary symptoms may indicate cauda equina syndrome (p. 1254). Occasionally, radiculopathy from HLD may present only with bladder symptoms which may improve after surgery.[5] Discectomy may improve bladder function, but this cannot be assured

Back pain per se is usually a minor component (only 1% of patients with acute low back pain have sciatica[6]), and when it is the only presenting symptom, other causes should be sought; see Low back pain (p. 1226). Sciatica has such a high sensitivity for disc herniation, that the likelihood of a clinically significant disc herniation[7] in the absence of sciatica is ≈ 1 in 1000. Exceptions include a central disc herniation which may cause symptoms of lumbar stenosis (i.e., neurogenic claudication) or a cauda equina syndrome.

75.5.2 Physical findings in radiculopathy

General information

Nerve root impingement gives rise to a set of signs and symptoms present to variable degrees. Characteristic syndromes are described for the most common nerve roots involved; see Nerve root syndromes (p. 1253).

In a series of patients referred to neurosurgical outpatient clinics for radiating leg pain, 28% had motor loss (yet only 12% listed motor weakness as a presenting complaint), 45% had sensory disturbance, and 51% had reflex changes.[8]

Findings suggestive of nerve root impingement include the following. ► Table 75.1 shows the sensitivity and specificity of some findings on the exam among patients with sciatica.

1. signs/symptoms of radiculopathy (► Table 75.1)
    a) pain radiating down LE
    b) motor weakness
    c) dermatomal sensory changes
    d) reflex changes: mental factors may influence symmetry[9]
2. positive nerve root tension sign(s): including Lasègue's sign (see below)
3. tenderness over the sciatic notch

Table 75.1 Sensitivity and specificity of physical findings for HLD in patients with sciatica[10]

Test	Comment	Sensitivity	Specificity
ipsilateral SLR	positive result: pain at < 60° elevation	0.80	0.40
crossed SLR	reproduction of contralateral pain	0.25	0.90
↓ ankle jerk	HLD usually at L5–1 (total absence increases specificity)	0.50	0.60
sensory loss	area of loss is poor in localizing level of HLD	0.50	0.50
↓ patellar reflex	suggests upper HLD	0.50	NA
Weakness			
knee extension (quadriceps)	HLD usually at L3–4	< 0.01	0.99
ankle dorsiflexion (anterior tibialis)	HLD usually at L4–5	0.35	0.70
ankle plantarflexion (gastrocs)	HLD usually at L5–1	0.06	0.95
great toe extension (EHL)	HLD at L5–1 in 60%, at L4–5 in 30%	0.50	0.70

Nerve root tension signs

Includes[11]:

1. Lasègue's sign: AKA straight leg raising (SLR) test. Helps differentiate sciatica from pain due to hip pathology. Test: with patient supine, raise afflicted limb by the ankle until pain is elicited[12] (should occur at < 60°, tension in nerve increases little above this angle). A positive test consists of leg pain or paresthesias in the distribution of pain (back pain alone does not qualify). The patient may also extend the hip (by lifting it off table) to reduce the angle. Although not part of Lasègue's sign, ankle dorsiflexion with SLR usually augments pain due to nerve root compression. SLR primarily tenses L5 and S1, L4 less so, and more proximal roots very little. Nerve-root compression produces a positive Lasègue's sign in ≈ 83% of cases[2] (more likely to be positive in patients < 30 yrs of age with HLD[13]). May be positive in lumbosacral plexopathy (p. 571). Note: flexing both thighs with the knees extended ("long-sitting" or sitting knee extension) may be tolerated further than flexing the single symptomatic side alone
2. Cram test: with patient supine, raise the symptomatic leg with the knee slightly flexed. Then, extend the knee. Results similar to SLR
3. crossed straight leg-raising test AKA Fajersztajn's sign: SLR on the painless leg causes contralateral limb pain (a greater degree of elevation is usually required than the painful side). More specific but less sensitive than SLR (97% of patients undergoing surgery with this sign have confirmed HLD[14]). May correlate with a more *central* disc herniation
4. femoral stretch test,[15] AKA reverse straight leg raising: patient prone, examiner's palm at popliteal fossa, knee is maximally dorsiflexed. Often positive with L2, L3, or L4 nerve root compression (e.g., in upper lumbar disc herniation), or with extreme lateral lumbar disc herniation (may also be positive in diabetic femoral neuropathy or psoas hematoma); in these situations SLR (Lasègue's sign) is frequently negative (since L5 & S1 are not involved)
5. "bowstring sign": once pain occurs with SLR, lower the foot to the bed by flexing knee, keeping the hip flexed. Sciatic pain ceases with this maneuver, but hip pain persists
6. sitting knee extension test: with patient seated and both hips and knees flexed 90°, slowly extend one knee. Stretches nerve roots as much as a moderate degree of SLR

Other signs useful in evaluation for lumbar radiculopathy

1. FABER: an acronym for Flexion ABduction External-Rotation, AKA FABERE test (the terminal "E" is for extension), AKA Patrick's test (after Hugh Talbot Patrick). A test of hip motion. Method: the hip and knee are flexed and the lateral malleolus is placed on the contralateral knee. The ipsilateral knee is gently displaced downward towards the exam table. This stresses the hip joint and does not usually exacerbate true nerve root compression. Often markedly positive in the presence of hip joint disease—e.g., trochanteric bursitis (p. 1332)—sacroiliitis or mechanical low-back pain
2. Trendelenburg sign: examiner observes pelvis from behind while patient raises one leg while standing. Normally the pelvis remains horizontal. A positive sign occurs when the pelvis tilts down toward the side of the lifted leg indicating weakness of the contralateral thigh abductors on the stance leg (primarily the gluteus medius, which is innervated by the superior gluteal nerve with contributions from L5 and some from L4 & S1)

3. crossed adductors: in eliciting patellar reflex (knee jerk (KJ)), the contralateral thigh adductors contract. In the presence of a hyperactive ipsilateral KJ it may indicate an upper motor neuron lesion; in the presence of a hypoactive ipsilateral KJ it may be a form of pathological spread, indicating nerve root irritability
4. Hoover sign[16]: to distinguish unilateral functional weakness of iliopsoas from organic weakness using synergistic contraction of the contralateral gluteus medius. The supine patient is asked to lift one leg off the bed against resistance from the examiner's hand. The examiner simultaneously places the palm of his/her other hand under the heel of the unlifted leg and gently lifts. Test 1: when the patient lifts the normal leg, if the paretic leg pushes down with more force than was exhibited on manual testing of the limb beforehand, the weakness is judged functional; if the force is equally weak the weakness is judged organic. Test 1 cannot be used if the hip extensor was normal beforehand. Test 2 (the better known test): the patient is asked to lift the weak leg. If the heel on the normal side lifts passively by the examiner, it suggests the weakness is functional (i.e., the patient is not trying). Not totally reliable[17,18]
5. abductor sign: an alternative to the Hoover test, to differentiate functional from organic weakness in the thigh abductors using synergistic contraction of the contralateral thigh abductors.[18] With the patient supine, the examiner places a hand on the lateral aspect of both legs. The patient is asked to abduct one leg, and then the other while the examiner applies resistance with his/her hand. The examiner mentally notes the response of the non-abducting LE. The results are as noted in ▶ Table 75.2

Table 75.2 Abductor sign

Abducting LE	Contralateral (nonabducting) LE	
	Organic weakness	Functional weakness
weak LE	maintains position	hyperadducts
normal LE	hyperadducts	maintains position

Nerve root syndromes

Due to the facts listed below, a herniated lumbar disc (HLD) usually spares the nerve root exiting at that interspace, and impinges on the nerve exiting from the neural foramen one level *below* (e.g., a L5–1 HLD usually causes S1 radiculopathy). This gives rise to the characteristic lumbar nerve root syndromes shown in ▶ Table 75.3.

Table 75.3 Lumbar disc syndromes

Syndrome	Level of herniated lumbar disc		
	L3–4	L4–5	L5–1
root usually compressed	L4	L5	S1
% of lumbar discs	3–10% (5% average)	40–45%	45–50%
reflex diminished	knee jerk[a] (Westphal's sign)	medial hamstring[b]	Achilles[a] (ankle jerk)
motor weakness	quadriceps femoris (knee extension)	tibialis anterior (foot drop) & EHL[c]	gastrocnemius (plantarflexion), ± EHL[c]
decreased sensation[d]	medial malleolus & medial foot	large toe web & dorsum of foot	lateral malleolus & lateral foot
pain distribution	anterior thigh	posterior LE	posterior LE, often to ankle

[a] **Jendrassik maneuver** may reinforce (see ▶ Table 30.2)
[b] medial hamstring reflex is unreliable (not always pure L5), may also stimulate adductors when eliciting
[c] see Weakness in ▶ Table 75.1 for breakdown
[d] sensory impairment is most common in the distal extremes of the dermatome[19]

Important applied anatomy in lumbar disc disease:

1. in the lumbar region, the nerve root exits *below* and in close proximity to the pedicle of its like-numbered vertebra
2. the intervertebral disc space is located well below the pedicle
3. not all patients have 5 lumbar vertebrae; see Localizing levels in spine surgery (p. 1719)

75.5.3 Cauda equina syndrome

Cauda equina syndrome (CES) is a clinical condition arising from dysfunction of multiple lumbar and sacral nerve roots within the lumbar spinal canal. To facilitate treatment, it is important to identify CES cases that are due to a surgially treatable condition. Since "no symptom or sign or combination can establish or exclude a diagnosis of CES,"[20,21] it has been recommended that MRI should be done as rapidly as possible.

► **Definition.** A 2009 review[22] found 17 different definitions for CES. For standardization, the following definition was proposed:

The diagnosis of cauda equina syndrome requires[22]:

1. one or more of the following:
    - bladder and/or bowel dysfunction
    - reduced sensation in the perineal region ("saddle anesthesia")
    - new onset of sexual dysfunction
2. possibly with neurologic deficit in the lower extremities (motor/sensory loss, reflex changes)

✖ It is recommended to avoid terms such as "complete", "incomplete", "true", "classic", "full blown", "partial"…[22]

Possible clinical findings in CES:

1. sphincter disturbance:
    a) urinary retention: the most consistent finding. Sensitivity ≈ 90% (at some point in time during course).[23,24] To evaluate acutely: have patient empty bladder and check post-void residual (by catheterization or with bladder ultrasound). Cystometrogram (when done) typically shows a hypotonic bladder with decreased sensation and increased capacity
    b) urinary and/or fecal incontinence[25]: some patients with urinary retention will present with overflow incontinence
    c) anal sphincter tone: assess resting tone and voluntary contraction. Diminished in 60–80%
2. "saddle anesthesia": the most common sensory deficit. Distribution: region of the anus, lower genitals, perineum, over the buttocks, posterior-superior thighs. Sensitivity ≈ 75%. Once total perineal anesthesia develops, patients tend to have permanent bladder paralysis[26]
3. significant motor weakness: usually involves more than a single nerve root (if untreated, may progress to paraplegia)
4. low back pain and/or sciatica (sciatica is usually bilateral, but may be unilateral or entirely absent; prognosis may be worse when absent or bilateral[24])
5. bilateral absence of Achilles reflex has been noted[27]
6. sexual dysfunction (usually not detected until a later time)

► **Categorization of CES.** Using MRI, a prospective series of 198 CES patients[21] classified them as:

1. scan positive CES: (24%) axial T2 MRI shows > 75% canal occlusion or no CSF signal. These patients were more likely to describe saddle anesthesia than the other groups
2. mixed scan results: (38%) radiographic evidence of nerve root compression or displacement not meeting criteria of scan positive CES (including crowding of cauda equina, nerve root compression or displacement)
3. scan negative CES: (31%) no nerve root compression or other radiographic explanation for CES symptoms. 96% did not have an explanatory diagnosis with 23 months mean follow-up. Etiologies included: stress incontinence, hyperactive bladder, spinal cord inflammation, spinal AVM, bladder inhibition due to pain or medication effects (Fowler's syndrome)

81% of patients referred to neurosurgery with CES have imaging that is normal or does not expain the symptoms (i.e., 81% do not have scan positive CES).[28]

Scan positive CES: usually due to compression of the cauda equina (the bundle of nerve roots below the conus medullaris arising from the lumbar enlargement and conus). See ► Table 55.9 for features to help differentiate CES from a conus lesion.

Etiologies of CES includes (items with a dagger (†) typically produce scan postivie CES):

1. compression of cauda equina
    a) massive herniated lumbar disc†: see below
    b) tumor
        - e.g., metastatic disease to the spine with epidural extension causing compression†
        - intravascular lymphomatosis (B-cell lymphoma) (p. 842): a circulating lymphoma without solid mass. Often presents with CNS findings: dementia, enhancing meninges on MRI, lymphoma cells in CSF, and CES

   c) free fat graft following discectomy† [29]
   d) trauma: fracture fragments compressing cauda equina†
   e) spinal epidural hematoma†
2. infection: may cause neurologic deficit from
   a) compression: typically from spinal epidural abscess complicating discitis or vertebral osteomyelitis†
   b) a significant number of cases of CES from infection may be due to vascular compromise resulting from local *septic thrombophlebitis*. This may carry a worse prognosis as surgical decompression cannot correct this mechanism
3. neuropathy:
   a) ischemic
   b) inflammatory
4. ankylosing spondylitis (p. 1365): etiology is often obscure (i.e., compression may be absent)

▸ **CES associated with lumbar disc herniation.** May be due to massive herniated disc, usually midline, most common at L4–5, often superimposed on a preexisting condition (spinal stenosis, tethered cord…).[25]

Prevalence of CES

1. 0.0004 in all patients with LBP[7]
2. only ≈ 1–2% of HLD that come to surgery[7]

Time course: CES tends to develop either acutely, or (less typically) slowly (prognosis is worse in the acute onset group, especially for return of bladder function, which occurred in only ≈ 50%).[23] 3 patterns[30]:

- Group I—sudden onset of CES symptoms with no previous low back symptoms
- Group II—previous history of recurrent backache & sciatica, the current episode combined with CES
- Group III—presentation with backache & bilateral sciatica that later develop CES

Timing of discectomy in CES: controversial, and the point of contention in numerous lawsuits. In spite of early reports emphasizing rapid decompression,[27] other reports found no correlation between the time to surgery after presentation and the return of function.[23,24] Some evidence supports the goal of performing surgery within 48 hours of onet (although performing surgery within 24 hours if possible is considered desirable, there is no statistically significant proof that delaying up to 48 hours is detrimental).[31,32]

Operative issues: some advise a bilateral laminectomy[25] (but this is not mandatory). Occasionally, when it is difficult to remove a very tense midline disc herniation, transdural removal may be helpful.[27]

75.6 Radiographic evaluation

See Radiographic evaluation under Low back pain (p. 1706). 70% of herniated discs that migrate do so *inferiorly*.

75.7 Nonsurgical treatment

75.7.1 Natural history of lumbar disc herniation

The rationale underlying the use of nonsurgical treatment measures for herniated disc is to impart symptomatic relief while providing an opportunity for the body's natural healing mechanisms to reduce the pressure on the nerve root. Spontaneous reduction of the volume of herniate disc material occurs as a result of a number of processes mediated by the immune system which involves activated macrophages in conjunction with inflammatory cytokines, angiogenesis inducing factor and matrix degrading enzymes.[33]

As a result, over 85% of patients with acute disc herniation will have symptomatic resolution *without* surgical intervention in an average of 6 weeks[34] (70% within 4 weeks[35]). There is often, but not always, a corresponding improvement in the MRI appearance.

75.7.2 Conservative treatment methodologies

Treatments may appear to be effective because of the high spontaneous resolution rate (85%). To adequately power a study to prove that a particular treatment is more effective than the natural history would require extremely large enrollment and would be quite costly. While conservative treatment can help control pain, unfortunately, to date there is no high-quality study to show statistically significant benefit of any particular conservative treatment modality compared to the natural history for the relief of radicular symptoms.

Conservative treatment measures employed for herniated disc are essentially the same as those used for low back pain in general (see nonsurgical treatment measures (p. 1237)).

75.8 Surgical treatment

75.8.1 General information

Numerous studies have shown beneficial effects of surgery for herniated lumbar discs. The oft-misunderstood Spine Patient Outcomes Research Trial (SPORT) (p. 1262) failed in its primary objective; however, it did demonstrate significant benefits of surgery when it was indicated.

75.8.2 Indications for surgery

No predictive factors have been identified that can determine which patients are likely to improve on their own and which would be better served with surgery.

Surgical indications in patients with a radiographically identified herniated disc that correlates with findings on the history and physical exam:

1. failure of non-surgical management. Because of the high spontaneous resolution rate (see Natural history (p. 1255)) most clinicians advocate waiting ≈ 5 to 8 weeks from the onset of radiculopathy before considering surgery (assuming none of the emergent items listed below applies)
2. "EMERGENT SURGERY": (i.e., before the 5–8 weeks of symptoms have lapsed). Indications:
   a) cauda equina syndrome (CES): (see below)
   b) *progressive* motor deficit (e.g., foot drop). NB: paresis of unknown duration is a doubtful indication for surgery[1,36,37] (no study has documented that there is less motor deficit in surgically treated patients with this finding[38]). However, the acute development or progression of motor weakness is considered an indication for rapid surgical decompression
   c) "urgent" surgery may be indicated for patients whose pain remains intolerable in spite of adequate narcotic pain medication
3. ± patients who do not want to invest the time in non-surgical treatment if it is possible that they will ultimately require surgery (relief is more rapid with surgery than conservative management[39])

75.8.3 Surgical intervention

Booking the case: Lumbar discectomy

Also see defaults & disclaimers (p. 25).

1. position: prone
2. equipment: microscope (if used), minimally invasive retractors (if used)
3. consent (in lay terms for the patient—not all-inclusive):
   a) procedure: surgery through the back to go between the bones and remove the piece of disc that is pressing on the nerve(s)
   b) alternatives: nonsurgical management
   c) complications: usual spine surgery complications (p. 1220), plus the disc can herniate again in the same place in ≈ 6% of cases, it is possible that a fragment of disc can be missed at the time of surgery, there might not be the amount of pain relief desired (back pain does not respond as well to surgery as nerve-root pain)

75.8.4 Surgical options for lumbar radiculopathy

Once it is decided to treat surgically, options include:

1. trans-canal approaches
   a) standard open lumbar laminectomy and discectomy: 65–85% reported no sciatica one year post-op compared to 36% for conservative treatment.[40] Long-term results (> 1 year) were similar. 10% of patients underwent further back surgery during the first year[40]
   b) "microdiscectomy"[41,42]: similar to standard procedure, but a smaller incision is utilized. Advantages may be cosmetic, shortened hospital stay, lower blood loss. May be more difficult to retrieve some fragments.[43 (p 1319),44] Overall efficacy is similar to standard discectomy[45]
   c) sequestrectomy: removal of only the herniated portion of the disc without entering the disc space to remove disc material from there
2. intradiscal procedures (see below): a number of procedures have been devised over the years to percutaneously treat HLD by creating a cavity within the disc. Some have been abandoned for various reasons, not the least of which is the controversy regarding the validity of the underlying premise that this can work
   a) chemonucleolysis: using chymopapain to enzymatically dissolve the disc (no longer used)
   b) automated percutaneous lumbar discectomy: utilizes a nucleotome
   c) percutaneous endoscopic intradiscal discectomy: see below
   d) intradiscal endothermal therapy (IDET or IDTA): see below
   e) laser disc decompression

75.8.5 Intradiscal surgical procedures (ISP)

ISPs (see below for specific procedures) are among the most controversial procedures for lumbar spine surgery. The theoretical advantage is that epidural scarring is avoided, and that a smaller incision or even just a puncture site is used. This is also purported to reduce postoperative pain and hospital stay (often performed as an outpatient procedure). The conceptual problem with ISPs is that they are directed at removing disc material from the center of the disc space (which is not producing symptoms) and rely on the reduced intradiscal pressure to decompress the herniated portion of the disc from the nerve root. Only ≈ 10–15% of patients considered for surgical treatment of disc disease are candidates for an ISP. ISPs are usually done under local anesthetic in order to permit the patient to report nerve root pain to identify impingement on a nerve root by the surgical instrument or needle. Overall, ISPs are not recommended until rigorous controlled trials prove the efficacy.[10]

Indications utilized by proponents of intradiscal procedures:

1. type of disc herniation: appropriate only for "contained" disc herniation (i.e., outer margin of anulus fibrosus intact)
2. appropriate level: best for L4–5 HLD. May also be used at L3–4. Difficult but often workable (utilizing angled instruments or other techniques) at L5–1 because of the angle required and interference by iliac crest
3. not recommended in presence of severe neurologic deficit[46]

Results:

"Success" rate (≈ pain free and return to work when appropriate) reported ranges from 37–75%.[47,48,49]

Automated percutaneous lumbar discectomy: AKA nucleoplasty. Utilizes a nucleotome[50] to remove disc material from the center of the intervertebral disc space. 1-year success rate of 37%. Complications include cauda equina syndrome from improper nucleotome placement.[51] In another study, nucleoplasty (with or without IDET [see below]) for HLD showed only modest reduction in pain at 9 months.[52]

Laser disc decompression: Insertion of a needle into the disc, and introduction of a laser fiberoptic cable through the needle to allow a laser to burn a hole in the center of the disc[53,54] (with or without endoscopic visualization).

The 2014 North American Spine Society Coverage Committee[55] position statement:

"Laser spine surgery in the **cervical** or **lumbar** spine is NOT indicated at this time. Due to lack of high quality clinical trials concerning laser spine surgery with the cervical or lumbar spine, it cannot be endorsed as an adjunct to open, minimally invasive, or percutaneous surgical techniques."

Percutaneous endoscopic lumbar discectomy (PELD): This term refers to an essentially intradiscal procedure indicated primarily for contained disc herniations, although some small "noncontained" fragments may be treatable.[56] No large randomized study has been done to compare the technique to the accepted standard, open discectomy (with or without microscope). In one report[57] of 326 patients with L4–5 HLD, only 8 (2.4%) met study criteria (no previous operation, failure of conservative treatment, imaging study proving disc protrusion followed by discography to R/O "disc perforation") for PELD. Of these 8, only 3 were reported as having a good result. This study is not adequate for evaluating the technique.

Intradiscal endothermal therapy (IDET): AKA intradiscal (electro)thermal anuloplasty (IDTA). Efficacy: 23–60% at 1 year for treating "internal disc disruption"[58] (radial fissures in the nucleus pulposus extending into the anulus fibrosus) which is purported to account for 40% of patients with chronic low back pain of unknown etiology.[59]

75.8.6 Adjunctive treatment in lumbar laminectomy

Epidural steroids following discectomy

Perioperative epidural steroids after routine surgery for lumbar degenerative disease may result in a small reduction of post-op pain, length of stay, and the risk of not returning to work at 1 year, but most of the evidence originates from studies not using validated outcome assessment that favor positive results, and further study is recommended (various agents, dosages, co-administered drugs, and delivery methods were reported).[60] However, the combination of systemic steroids at the start of the case (Depo-Medrol® 160 mg IM and methylprednisolone sodium succinate (Solu-Medrol®) 250 mg IV) combined with infiltration of 30 ml of 0.25% bupivacaine (Marcaine®) into the paraspinal muscles at incision and closure, may reduce hospital stay and post-op narcotic requirements.[61]

75.8.7 Methods to reduce scar formation

Epidural free fat graft

The use of an autogenous free fat graft in the epidural space has been employed in an attempt to reduce post-op epidural scar formation. Opinion varies widely as to the effectiveness, some feel it is helpful, others feel it actually exacerbates scarring.[62] In some patients, no evidence of the graft will be found on reoperation years later. The fat graft can very rarely be a cause of nerve root compression[63] or cauda equina syndrome[29] within the first few days post-op, and there is a case report of compression 6 years following surgery.[64]

Other measures

Other measures include the placement of barrier films or gels. There are numerous products available, none has been shown to have reproducible benefit.

75.8.8 Risks of lumbar laminectomy

General information

Overall risk of mortality in large series[65,66]: 6 per 10,000 (i.e., 0.06%), most often due to septicemia, MI, or PE. Complication rates are very difficult to determine accurately,[40] but the following is included as a guideline.

Common complications

1. infection:
   a) superficial wound infection: 0.9–5%[67] (risk is increased with age, long-term steroids, obesity, ? DM): most are caused by *S. aureus*; see Laminectomy wound infection (p. 377) for management
   b) deep infection: < 1% (see below under Uncommon complications)
2. increased motor deficit: 1–8% (some transient)
3. unintended "incidental" durotomy (p. 1260) (the term "unintended durotomy" has been recommended in preference to "dural tear," see below): incidence is 0.3–13% (risk increases to ≈ 18% in redo operations).[68] Possible sequelae include those listed in ► Table 75.4
   a) CSF fistula (external CSF leak): the risk of a CSF fistula requiring operative repair is ≈ 10 per 10,000[65]
   b) pseudomeningocele: 0.7–2%[68] (may appear similar radiographically to spinal epidural abscess (SEA), but post-op SEA often enhances, is more irregular, and is associated with muscle edema)
4. recurrent herniated lumbar disc (same level either side) (p. 1267): 4% (with 10-year follow-up)[69]
5. postoperative urinary retention (POUR) (p. 1260): usually temporary, but may delay hospital discharge

Uncommon complications

1. direct injury to neural structures. For large disc herniations, consider a bilateral exposure to reduce risk
2. injury to structures anterior to the vertebral bodies (VB): injured by breaching the anterior longitudinal ligament (ALL) through the disc space, e.g., with pituitary rongeur. The depth of disc space penetration with instruments should be kept ≤ 3 cm, since 5% of lumbar discs had diameters as small as 3.3 cm.[70] Asymptomatic perforations of the ALL occur in up to 12% of discectomies. Breach of the ALL risks potential injuries to:
   a) great vessels[71]: risks include potentially fatal hemorrhage, and arteriovenous fistula which may present years later. Most such injuries occur with L4–5 discectomies. Only ≈ 50% bleed into the disc space intraoperatively, the rest bleed into the retroperitoneum. Emergent laparotomy or endovascular treatment[72] is indicated, preferably by a surgeon with vascular surgical experience, if available. Mortality rate is 37–67%
      - aorta: the aortic bifurcation is on the left side of the lower part of the L4 VB, and so the aorta may be injured above this level
      - below L4, the common iliac arteries may be injured
      - veins (more common than arterial injuries): vena cava at and above L4, common iliac veins below L4
   b) ureters
   c) bowel: at L5–1 the ileum is the most likely viscus to be injured
   d) sympathetic trunk
3. wrong site surgery: incidence in self-reporting survey was 4.5 occurrences per 10,000 lumbar spine operations.[73] Factors identified as potential contributors to the error: unusual patient anatomy, not performing localizing radiograph. 32% of responding neurosurgeons indicated that they removed disc material from the wrong level at some time in their career
4. rare infections:
   a) meningitis
   b) deep infection: < 1%. Including:
      - discitis (p. 390): 0.5%
      - spinal epidural abscess (SEA) (p. 381): 0.67%
5. cauda equina syndrome: may be caused by post-op spinal epidural hematoma (see below). Incidence was 0.21% in one series of 2842 lumbar discectomies[74] and 0.14% in a series of 12,000 spine operations.[75] Red flags: urinary retention, anesthesia that may be saddle or *bilateral* LE
6. postoperative visual loss (POVL)[76]: (see below)
7. complications of positioning:
   a) compression neuropathies: ulnar, peroneal nerves. Use padding over elbows and avoid pressure on posterior popliteal fossa
   b) anterior tibial compartment syndrome: due to pressure on anterior compartment of leg (reported with Andrew's frame). An orthopedic emergency that may require emergent fasciotomy
   c) pressure on the eye: corneal abrasions, damage to the anterior chamber
   d) cervical spine injuries during positioning due to relaxed muscles under anesthesia
8. post-op arachnoiditis (p. 1243): risk factors include epidural hematoma, patients who tend to develop hypertrophic scar, post-op discitis, and intrathecal injection anesthetic agents or steroids. Surgical treatment for this is disappointing. Intrathecal depo-medrol may provide short-term relief (in spite of the fact that steroids are a risk factor for the development of arachnoiditis).
9. thrombophlebitis and deep-vein thrombosis with risk of pulmonary embolism (PE)[65]: 0.1%; see Thromboembolism in neurosurgery (p. 176)
10. complex regional pain syndrome AKA reflex sympathetic dystrophy (RSD) (p. 525): reported in up to 1.2% of cases, usually after posterior decompression with fusion, often following reoperations[77] with onset 4 days to 20 weeks post-op. See also critique of RSD (p. 526). Treatment includes some or all of: PT, sympathetic blocks, oral methylprednisolone, removal of hardware if any
11. very rare: Ogilvie's syndrome (pseudo-obstruction ("ileus") of the colon). Usually seen in hospitalized/debilitated patients. May be related to narcotics, electrolyte deficiencies, possibly from chronic constipation. Also reported following spinal surgery/trauma, spinal/epidural anesthesia, spinal metastases, & myelography[78]

Postoperative urinary retention

Post-op urinary retention (ironically, abbreviated POUR) is very common, especially following lumbar spine surgery. It encompasses a subset of conditions associated with urinary retention (p. 95) in general.

1. spinal cord or cauda equina compression: often (but not always) accompanied by other new neurologic deficit. When this is the result of surgery, it may be due to:
   a) nerve or spinal cord compression: in the post-op setting, possible sources include: hematoma, instrumentation (e.g., pedicle screws), bone graft material, fragments from bone fracture
   b) nerve or spinal cord injury during surgery
2. urinary tract infection (UTI)
3. immobility
4. narcotics
5. constipation

Management

Examine patient for: new sensory level, other neurologic deficit that is new compared to pre-op

1. STAT MRI or CT of the surgical site to rule out hematoma
2. U/A and urine culture and treat any identified UTI
3. treat constipation with stool softeners and/or laxatives as appropriate
4. preferrably, teach patient how to perform clean intermittent catheterizations (CIC) q 4 hour and PRN. If this is not practical, send the patient home with a Foley (indwelling) urinary catheter
5. start Flomax (0.4 mg daily) if not contraindicated & send patient home on this
6. set up appointment with urology (typically 10–14 days post op) for a voiding trial. This is usually an early morning appointment at which time the urology service will remove the Foley catheter (if present) and check a post void residual (PVR) either with a bladder scan (ultrasound) or with a straight catheterization after a couple hours to assess urinary retention. Sometimes cystoscopy or urodynamics will be done at the same appointment

Unintended durotomy

Unintentional opening of the dura during spinal surgery has an incidence of 0–14%.[79]

Terminology: The terms “unintended durotomy,” “incidental durotomy,”[79] or even just “dural opening,” have been recommended in preference to “dural tear” which may imply carelessness[68] when none was present. Dural openings have been associated with one or more alleged complications or sequelae in medical malpractice suits involving surgery on the lumbar spine.

The injury: By itself, opening the dura intentionally or otherwise is not expected to have a deleterious effect on the patient.[68,80] In fact, dural opening is often a standard part of the operation for intradural disc herniation,[81] tumors, etc. Although not frequent (for incidence, see above), unintended durotomy is not an unusual occurrence, and alone, is not considered an act of malpractice. However, it may result from an event or events that produce more serious injuries. These events and injuries should be dealt with on their own merits.

In the SPORT, there was a 9% incidence of unintended durotomy in patients undergoing first-time open laminectomy.[82] There were no long-term differences in nerve root injuries, mortality, additional operations, or outcome measures. Short-term differences included longer inpatient stay, increased blood loss, and duration of surgery.[82] In a Dartmouth study of 25 durotomy patients, there was no increase in post-op nerve root injury, wound infection, or wound hematoma in the durotomy group.[83]

Possible sequelae include those listed in ▶ Table 75.4. A CSF leak may produce “spinal headache” (p. 1816) with its associated symptoms and if it breaches the skin it may be a risk factor for

Table 75.4 Possible sequelae of dural opening

Well documented
1. CSF leak a) contained: pseudomeningocele b) external: CSF fistula 2. herniation of nerve roots through opening 3. associated nerve root contusion, laceration, or injury to the cauda equina 4. CSF leak collapses the thecal sac and may increase blood loss from epidural bleeding
Less well documented
1. arachnoiditis 2. chronic pain 3. bladder, bowel, and/or sexual dysfunction

meningitis. Pain or sensory/motor deficits may be associated with injuries to nerve roots or delayed herniation of nerve roots through the dural opening.

Etiologies: Potential causes are many, and include[68]: unanticipated anatomic variations, adhesion of the dura to removed bone, slippage of an instrument, an obscured fold of dura caught in a rongeur or curette, thinning of the dura in cases of longstanding stenosis, and the possibility of a delayed CSF leak caused by perforation of the dura when it expands onto a surgically created spicule of bone.[84] The risk may be increased with anterior decompression for OPLL, with revision surgery, and with the use of high-speed drills.[79]

Treatment: If the opening is recognized at the time of surgery, watertight primary closure (with or without patch graft) should be attempted with nonabsorbable suture if at all possible to prevent pseudomeningocele and/or CSF fistula. A cottonoid placed over the opening prevents aspiration of nerve roots.[85] Care must be taken to avoid incorporating a nerve root into the closure. Most repairs will be accomplished with no complication or sequelae to the patient. When the opening is in the far (anterior) side of the dura, consideration may be given to intradural repair accessed through a posterior durotomy which is subsequently closed (this may risk additional injury to the nerve roots). Biocompatible fixatives (e.g., fibrin glue[79]) may be used to supplement primary closure.

Primary repair may be impossible in some situations (e.g., when the opening cannot be found or accessed, as is sometimes the case when it occurs on the nerve root sleeve) and alternatives here include placement of a fat or muscle graft over the suspected leak site, use of the patient's own blood for a "blood patch" (one technique is to have the anesthesiologist draw ≈ 5–10 ml of the patient's blood from an arm vein, keeping it in the syringe for several minutes until it starts to coagulate, and then to have the anesthesiologist inject the blood onto the dura), use of gelfoam, fibrin glue… Some recommend that the wound not be drained post-op, with a watertight closure of fascia, fat, and skin to add to the barrier. Others use a subcutaneous drain or epidural catheter. CSF diversionary procedures (e.g., through a drain inserted 1 or more levels away) may also be used.

Although bed rest × 4–7 days is often advocated to reduce symptoms and facilitate healing, when watertight closure has been achieved, normal post-op mobilization is not associated with a high failure rate (bed rest is recommended if symptoms develop).[79]

In one report of 8 patients with leaks that appeared post-op, reoperation was avoided when treated by resuturing the skin under local anesthesia, followed by bed rest in slight Trendelenburg position (to reduce pressure on the leakage site), broad-spectrum antibiotics and antibiotic ointment over the skin incision, and daily puncture and drainage of the subcutaneous collection.[86]

See other treatment measures for H/A associated with CSF leak (p. 1256).

Postoperative visual loss (POVL)

1. ischemic optic neuropathy[87]: the most common cause of the very uncommon postoperative loss of vision. Often bilateral. Usually associated with significant blood loss (median: 2 L), and/or prolonged operative time (≥ 6 hrs). All cases had anesthetic time > 5 hrs or blood loss > 1 L. Blood loss can cause hypotension (may cause release of endogenous vasoconstrictors in addition to reduced blood flow due to low hemodynamic pressure) and increased platelet aggregation. Is not due to direct pressure on the globe in most cases, and can occur at any age and even in otherwise healthy patients. No association with age, HTN, atherosclerosis, smoking, or DM.
   The blindness can be extensive and is often permanent. Prevention is critical since there is no known effective treatment.[88]
   a) posterior ischemic optic neuropathy (PION)[87]: may follow surgery (surgical PION). Risk factors as above, plus:
      - surgery in the *prone* position (can cause periorbital edema, and rarely, direct pressure on the orbit)
      - lack of tight glycemic control
      - use of Trendelenburg position
      - hemodilution or overuse of crystalloid vs. colloid (blood) fluid replacement
      - prolonged hypotension
      - cellular hypoxia
      - decreased renal perfusion
   b) 6 independent risk factors for POVL[88]
      - male gender: odds ratio (OR) = 2.53
      - obesity: by clinical assessment or BMI ≥ 30 OR = 2.83
      - use of Wilson frame: OR = 4.30
      - length of anesthesia: OR = 1.39 per hour
      - EBL: OR = 1.34 per liter
      - use of colloid as a percentage of nonblood replacement: less certain (small difference). OR = 0.67 per 5% colloid

   c) anterior ischemic optic neuropathy (AION): divided into arteritic (as with giant cell arteritis (GCA)) and nonarteritic (common with DM)
2. central retinal artery occlusion
3. cortical blindness: from occipital lobe infarction possibly due to embolism

75.8.9 Post-op care

Post-op orders

The following are guidelines for postoperative orders for a lumbar laminectomy without intraoperative complications; variations between surgeons and institutions must be taken into consideration:

1. admit post-anesthesia care unit (PACU)
2. vital signs on the nursing unit: q 2° × 4 hrs, q 4° × 24°, then q 8°
3. activity: up with assist, advance as tolerated
4. nursing care
   - I's & O's
   - intermittent catheterization q 4–6° PRN no void
   - optional: TED hose (may reduce risk of DVT) or PCB
   - optional (if drain used): empty drain q 8° and PRN
5. diet: clear liquids, advance as tolerated
6. IV: D5 1/2 NS + 20 mEq KCl/l @ 75 ml/hr, D/C when tolerating PO well (after antibiotics D/C'd if prophylactic antibiotics are used)
7. meds
   - laxative of choice (LOC) PRN
   - sodium docusate (e.g., Colace®) 100 mg PO BID when tolerating PO (stool softener, does not substitute for LOC)
   - optional: prophylactic antibiotics if used at your institution
   - acetaminophen (Tylenol®) 325 mg 1–2 PO or PR q 6° PRN
   - narcotic analgesic
   - optional: steroids are used by some surgeons to reduce nerve-root irritation from surgical manipulation
8. labs
   - optional (if significant blood loss during surgery): CBC

Post-op check

In addition to routine, the following should be checked:

1. strength of lower extremities, especially muscles relevant to nerve root, e.g., gastrocnemius for L5–1 surgery, EHL for L4–5 surgery…
2. appearance of dressing: look for signs of excessive bleeding, CSF leak…
3. signs of cauda equina syndrome (p. 1254), e.g., by post-op spinal epidural hematoma
   a) loss of perineal sensation ("saddle anesthesia")
   b) inability to void: may not be unusual after lumbar laminectomy, more concerning if accompanied by loss of perineal sensation
   c) pain out of the ordinary for the post-op period
   d) weakness of multiple muscle groups

Any new neurologic deficit should prompt rapid evaluation for spinal epidural hematoma[75] (EDH). Delayed deficits may be due to EDH or epidural abscess. Post-op films in the recovery room can rule out graft or hardware malposition for fusions or instrumentation procedures, or changes in alignment. The diagnostic test of choice is MRI. If contraindicated or not available, CT/myelography may be indicated. An extradural defect immediately post-op suggests EDH.

75.8.10 Outcome of surgical treatment

In a series of 100 patients undergoing discectomy, at 1 year post-op 73% had complete relief of leg pain and 63% had complete relief of back pain; at 5–10 years the numbers were 62% for each category.[2] At 5–10 years post-op, only 14% felt that the pain was the same or worse than pre-op (i.e., 86% felt improved), and 5% qualified as having a failed back surgery syndrome (a heterogeneous, not precisely defined term, here meaning not returned to work, requiring analgesics, receiving worker's compensation, see Failed back surgery syndrome (p. 1243)). Other studies have confirmed that LBP improves in a significant number of patients with a HLD undergoing discectomy without fusion.[89,90]

Attempts to compare relative merits of conservative treatment vs. surgery have failed to yield meaningful answers due to severe methodologic flaws. This includes the Spine Patient Outcomes Research Trial (SPORT),[89,91] with methodologic flaws[39] that included large numbers of patient cross-overs from the surgical to the nonoperative arm, and thus SPORT more nearly approximated the current methodology of surgical selection than an actual RCT.[39] Earlier attempts at randomized trials also suffered from methodologic flaws.[1] Conclusions that can be drawn from these studies[39]: most patients with manageable or improving pain and less disability typically choose conservative treatment and most have improvement in symptoms, whereas patients with severe, persistent, or worsening pain and/or neurologic deficit are more likely to choose surgery with a resultant excellent outcome. Furthermore, surgery patients had more rapid symptom relief and did statistically significantly better on virtually all primary and secondary outcome measures throughout the 2-year SPORT.

In patients with a diminished knee-jerk or ankle-jerk pre-op, 35% and 43% (respectively) still had reduced reflexes 1 year post-op[8]; reflexes were lost post-op in 3% and 10% respectively. The same study found that motor loss was improved in 80%, aggravated in 3%, and was newly present in 5% post-op; and that sensory loss was improved in 69% and was worsened in 15% post-op.

Foot drop: severe or complete paralysis of ankle dorsiflexion occurs in 5–10% of HLD, and about 50% of cases recover with or without treatment. Discectomy does not improve the outcome, especially in cases of painless foot drop.[38]

See Recurrent disc herniation (p. 1267).

75.9 Herniated upper lumbar discs (levels L1–2, L2–3, and L3–4)

75.9.1 General information

L4–5 & L5–1 herniated lumbar discs (HLD) account for most cases of HLD (realistically ≈ 90%, possibly as high as 98%[7]). 24% of patients with HLD at L3–4 have a past history of an HLD at L4–5 or L5–1, suggesting a generalized tendency towards disc herniation. In a series of 1,395 HLDs, there were 4 at L1–2 (0.28% incidence), 18 at L2–3 (1.3%), and 51 at L3–4 (3.6%).[92]

75.9.2 Presentation

Typically presents with LBP, onset following trauma or strain in 51%. With progression, paresthesias and pain in the anterior thigh occur, with complaints of leg weakness (especially on ascending stairs).

75.9.3 Signs

Quadriceps femoris was the most common muscle involved, demonstrating weakness and sometimes atrophy.

Straight leg raising was positive in only 40%. Psoas stretch test was positive in 27%. Femoral stretch test may be positive (p. 1252).

50% had reduced or absent knee jerk; 18% had ankle jerk abnormalities; reflex changes were more common with L3–4 HLD (81%) than L1–2 (none) or L2–3 (44%).

75.10 Extreme lateral lumbar disc herniations

75.10.1 General information

Definition: herniation of a disc in the foraminal zone or the extraforaminal zone (▶ Fig. 75.1). Herniations in the foraminal zone are located anterior to the facet joint, and are also called foraminal disc herniations.

Foraminal disc herniations typically involve the nerve root exiting at that level (e.g., an L4–5 foraminal disc herniation will involve the L4 nerve root) (see ▶ Fig. 75.2). The dorsal root ganglion (DRG) containing the cell bodies of the sensory nerve is also located in the foramen within the nerve root sheath. Compression of the DRG by herniated disc material may be associated with a worse outcome.

Disc herniations in the extraforaminal zone occasionally involve the nerve root exiting at that level; however, disc herniation here and those herniating anterior to the spine may not result in any nerve root involvement.

Incidence (▶ Table 75.5): 3–10% of herniated lumbar discs (HLD) (series with higher numbers[93] include some HLD that are not truly extreme lateral).

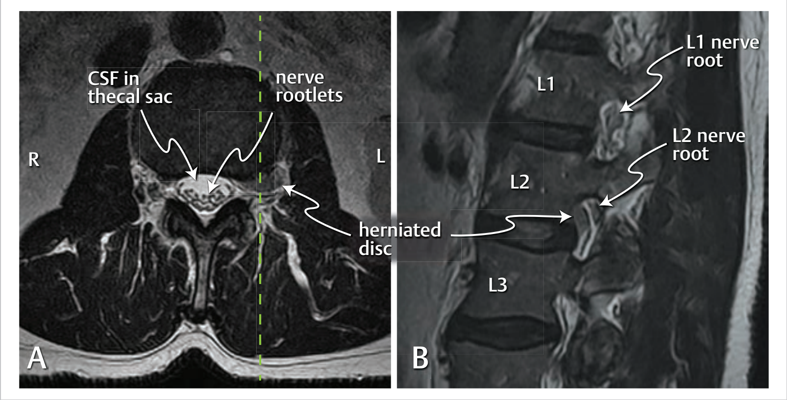


Fig. 75.2 Foraminal disc herniation.
Image: T2 MRI showing a large left-sided L2–3 disc herniation with a foraminal and an extraforaminal zone component.
A: axial cut through the L2–3 disc, B: parasagittal cut through the left neural foramina (slice location shown by green broken line) showing compression of the exiting left L2 nerve root. Note the normal left L1 nerve root.

Table 75.5 Incidence of extreme lateral HLD by level[a]

Disc level	No.	%
L1–2	1	1
L2–3	11	8
L3–4	35	24
L4–5	82	60
L5–S1	9	7

[a]series of 138 cases[93]

Occurs most commonly at *L4–5* and next at L3–4 (see ▶ Table 75.5), thus L4 is the most common nerve involved and L3 is next. With a clinical picture of an upper lumbar nerve root compression (i.e., radiculopathy with negative SLR), chances are ≈ 3 to 1 that it is an extremely lateral HLD rather than an upper lumbar disc herniation.

Differs from the more common central and subarticular zone HLD in that:

- the nerve root involved is usually the one exiting *at* that level (c.f. the root exiting at the level below)
- straight leg raising (SLR) (p. 1252) is negative in 85–90% of cases ≥ 1 week after onset (excluding double herniations; ≈ 65% will be negative if double herniations are included); may have positive femoral stretch test
- pain is reproduced by lateral bending to the side of herniation in 75%
- higher incidence of extruded fragments (60%)
- higher incidence of double herniations on the same side at the same level (15%)
- pain tends to be more severe (may be due to the fact that the dorsal root ganglion may be compressed directly) and often has more of a burning dysesthetic quality

Presentation

Quadriceps weakness, reduction of patellar reflex, and diminished sensation in the L3 or L4 dermatome are the most common findings.

75.10.2 Differential diagnosis

1. lateral recess stenosis or superior articular facet hypertrophy
2. retroperitoneal hematoma or tumor

3. diabetic neuropathy (amyotrophy) (p. 572)
4. spinal tumor
   a) benign (schwannoma or neurofibroma)
   b) malignant tumors
   c) lymphoma
5. infection
   a) localized (spinal epidural abscess)
   b) psoas muscle abscess
   c) granulomatous disease
6. spondylolisthesis (with pars defect)
7. compression of conjoined nerve root
8. on MRI, enlarged foraminal veins may mimic extreme lateral disc herniation

75.10.3 Radiographic diagnosis

NB: if actively sought, many *asymptomatic* far-lateral disc herniations may be demonstrated on MRI or CT. Careful clinical correlation is usually required.

MRI: diagnostic test of choice. Sagittal views through the neural foramen may help demonstrate the disc herniation.[94] MRI may have ≈ 8% false positive rate due to presence of enlarged foraminal veins that mimic extreme lateral HLD.[95]

Myelography: myelography alone is rarely diagnostic (usually requires post-myelo CT).[96,97] Fails to disclose the pathology in 87% of cases due to the fact that the nerve root compression occurs distal to the nerve root sleeve (and therefore beyond the reach of the dye).[98]

CT scan[97]: reveals a mass displacing epidural fat and encroaching on the intervertebral foramen or lateral recess, compromising the emerging root. Or, may be lateral to foramen. Sensitivity is ≈ 50% and is similar with post-myelographic CT.[98] Post-discography CT[98,99] has also been able to demonstrate.

75.10.4 Surgical treatment

NB: compression of the dorsal root ganglion may result in a slower recovery from discectomy and overall less satisfying outcome than with the more commonplace paramedian disc herniation.

Foraminal discs

Usually requires mesial facetectomy to gain access to the region lateral to the dural sac without undue retraction on nerve root or cauda equina. Caution: total facetectomy combined with discectomy may result in a high incidence of instability (total facetectomy alone causes ≈ 10% rate of slippage), although other series found this risk to be lower (≈ 1 in 33[100,101]). An alternative technique is to remove just the lateral portion of the superior articular facet below.[102] Endoscopic techniques may be well suited for herniated discs in this location.[103] Even with a small amount of unroofing the foramen, it is often enough to adequately fish disc fragments out of the foramen with a nerve hook.

Discs herniated beyond (lateral to) the foramen

Numerous approaches may be used, including:
1. traditional midline hemilaminectomy: the ipsilateral facet must be partially or completely removed. The safest way to find the exiting nerve root is to take the laminectomy of the inferior portion of the upper vertebral level (e.g., L4 for a L4–5 HLD) high enough to expose the nerve root axilla, and then follow the nerve laterally through the neural foramen by removing the facet until the HLD is identified
2. lateral approach (i.e., extra-canal) through a paramedian incision.[104] Advantages: the facet joint is preserved (facet removal combined with discectomy may lead to instability), muscle retraction is easier. Disadvantages: unfamiliar approach for most surgeons and the nerve cannot be followed medial to lateral. A localizing X-ray is taken with a spinal needle. A 4–5 cm vertical skin incision is made 3–4 cm lateral to the midline on the side of the disc herniation. The incision is taken down to the thoracolumbar fascia and the subcutaneous tissue is dissected off the fascia. Above L4, one may palpate the groove between multifidus (medial) and longissimus (lateral), where the fascia is incised. The facet joint is palpated, and blunt dissection is used to gain access to the lateral facet joint and transverse processes above and below the level of the disc herniation. The correct level is confirmed on X-ray using a probe as a marker. The intertransversarius muscle and fascia are divided. Care must be taken to avoid mechanical and electrocautery injury to the nerve

and dorsal root ganglion (which lies immediately beneath the intertransverse ligament). The radicular artery, vein, and nerve root are located just beneath the transverse processes, usually slightly medial to this position. The nerve root hugs the pedicle of the level above as it exits the neural foramen (palpating this e.g., with a dental dissector helps locate it), and it may be splayed over the herniated disc fragment. If more medial exposure is necessary, the lateral facet joint may be resected. The HLD is removed. Additional removal of disc material from the disc space may be performed with down-biting pituitary rongeurs. Extracanal approach to L5–1 requires removal of part of the sacral ala in order to access the space caudal to the L5 transverse process

75.11 Lumbar disc herniations in pediatrics

Less than one percent of surgery for herniated lumbar disc is performed on patients between the ages of 10 and 20 yrs (one series at Mayo found 0.4% of operated HLD in patients < 17 yrs of age[105]). These patients often have few neurologic findings except for a consistently positive straight leg raising test.[106] Herniated disc material in youths tends to be firm, fibrous, and strongly attached to the cartilaginous endplate unlike the degenerated material usually extruded in adult disc herniation. Plain radiographs disclosed an unusually high frequency of congenital spine anomalies (transitional vertebra, hyperlordosis, spondylolisthesis, spina bifida…). 78% did well after their first operation.[105]

75.12 Intradural disc herniation

Herniation of a fragment of disc into the thecal sac, or into the nerve root sleeve (the latter sometimes referred to as "intraradicular" disc herniation) has been recognized with a reported incidence of 0.04–1.1% of disc herniations.[81,107] Although it may be suspected on the basis of pre-op MRI or myelography, the diagnosis is rarely made preoperatively.[107] Intraoperatively, it may be suggested by the appreciation of a tense firm mass within the nerve root sleeve or by the negative exploration of a level with obvious clinical signs and clear-cut radiographic abnormalities (after verifying that the correct level is exposed).

Surgical treatment:

Although a surgical dural opening may be utilized,[81] others have found this to be necessary in a minority of cases.[108]

75.13 Intravertebral disc herniation

75.13.1 General information

AKA Schmorl's node or nodule. Named for German pathologist Christian Georg Schmorl (1861–1932) the term was first used in 1971.[109] AKA Schmor's (no "l") nodule AKA Geipel hernia.[110] Disc herniation through the cartilaginous endplate into the cancellous bone of the vertebral body (VB) (AKA intraspongious disc herniation). Often an incidental finding on X-ray or MRI. Clinical significance is controversial. May produce low back pain initially that lasts ≈ 3–4 months after onset. Diffuse displacement (as may be seen in osteoporosis) is sometimes referred to as a balloon disc.[111]

75.13.2 Clinical findings

During the acute (symptomatic) phase, patients may exhibit LBP that is aggravated by weight bearing and movement. There may be tenderness to percussion or manual compression over the involved segment.

75.13.3 Radiographic findings

MRI: the extrusion of disc material into the VB is easily appreciated on sagittal images (▶ Fig. 75.3). It has been suggested[112] that acute (symptomatic) lesions may appear differentiated from chronic (asymptomatic) lesions by the presence of MRI findings of inflammation in the bone marrow immediately surrounding the node as outlined in ▶ Table 75.6.

CT: demonstrates defect in endplate and vertebral body since disc material has a significantly lower density than bone.

Plain X-ray: ≤ 33% may be seen on plain X-rays.[113] They may not be detectable acutely until sclerotic osseous bone casting develops.

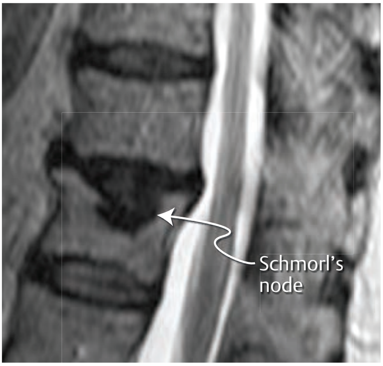

Fig. 75.3 Schmorl's node. Image: sagittal T2 MRI showing herniation of the intervertebral disc into the superior endplate of the vertebral body below the disc (Schmorl's node).
The lack of high intensity in the adjacent bone marrow on T2 MRI is compatible with a chronic condition.

Table 75.6 MRI signal intensity in bone marrow surrounding a Schmorl's node[a]

Lesion	T1WI	T2WI
symptomatic (acute)	low	high
asymptomatic (chronic)	high[b]	low[b]

[a]signal intensity in surrounding marrow
[b]the same as normal marrow

75.13.4 Treatment

Conservative treatment is indicated, usually consisting of non-steroidal anti-inflammatory drugs (NSAIDs). Occasionally stronger pain medication and/or lumbar bracing may be required. Surgery is rarely indicated.

75.13.5 Outcome

With conservative treatment, symptoms generally resolve within 3–4 months of onset (as with most vertebral body fractures).

75.14 Recurrent herniated lumbar disc

75.14.1 General information

Rates quoted in the literature range from 3–19% with the higher rates usually in series with longer follow-up.[114] In an individual series with 10-year mean F/U, the rate of recurrent disc herniation was 4% (same level, either side), one third of which occurred during the 1st year post-op (mean: 4.3 yrs).[69] A *second* recurrence at the same site occurred in 1% in another series[114] with mean F/U of 4.5 yrs. In this series,[114] patients presenting for a second time with disc herniation had a recurrence at the same level in 74%, but 26% had an HLD at another level. Recurrent HLD occurred at L4–5 more than twice as often as L5–1.[114]

It is often possible for a smaller volume of recurrent herniated disc to cause symptoms than in a "virgin back," due to the fact that the nerve root is often fixated by scar tissue and has little ability to deviate away from the fragment.[62]

75.14.2 Treatment

Initial recommended treatment is as with a first-time HLD. Nonsurgical treatment should be utilized in the absence of progressive neurologic deficit, cauda equina syndrome (CES), or intractable pain.

75.15 Surgical treatment

Disagreement occurs regarding optimal treatment. See **Practice guideline: Lumbar fusion for disc herniation** (p. 1240).

Surgical outcome:

As with first-time HLD, the outcome from surgical treatment is worse in worker's compensation cases and in patients undertaking litigation, only ≈ 40% of these patients benefit.[114,115] A worse prognosis is also associated with: patients with < 6 mos relief after their first operation, cases where fibrosis without recurrent HLD is found at operation.

75.16 Spinal cord stimulation

One study actually showed a better response rate to spinal cord stimulation than to reoperation.[116] Since surgery for recurrent HLD carries a higher risk of dural and nerve root injury, and a lower success rate than first-time operations, this may be a viable option for some patients.

76 Thoracic Disc Herniation

76.1 General information

Key concepts

- comprise only 0.25% of herniated discs, and < 4% of operations for herniated disc
- usually occur at or below T8 (the more mobile portion of the thoracic spine)
- frequently calcified ∴ get CT through disc (may affect choice of surgical approach)
- primary indications for surgery: refractory pain, progressive myelopathy
- surgical treatment: laminectomy is usually not appropriate for midline or calcified herniated discs

Account for 0.25–0.75% of all protruded discs.[1] 80% occur between the 3rd and 5th decades. 75% are below T8 (the more mobile portion of the thoracic spine), with a peak of 26% at T11–12. 94% were centrolateral and 6% were lateral.[2] A history of trauma may be elicited in 25% of cases.

Most common symptoms: pain (60%), sensory changes (23%), motor changes (18%). With thoracic radiculopathy, pain and sensory disturbance is in a band-like distribution radiating anteriorly and inferiorly along the involved root's dermatome (paralleling a rib). Motor involvement is difficult to document.

76.2 Evaluation

1. MRI: noncontrast thoracic MRI is the mainstay of diagnosis. If MRI is contraindicated, a thoracic CT/myelogram is the second choice
2. CT scan: noncontrast thoracic CT scan should be routinely obtained to determine if it is a "soft disc" (noncalcified) (see ▶ Fig. 76.1) or a "hard disc" (calcified) (see ▶ Fig. 76.2) which can have a profound effect on the choice of approach and the removal technique. CT also delineates the bony detail which is helpful if instrumentation is needed.

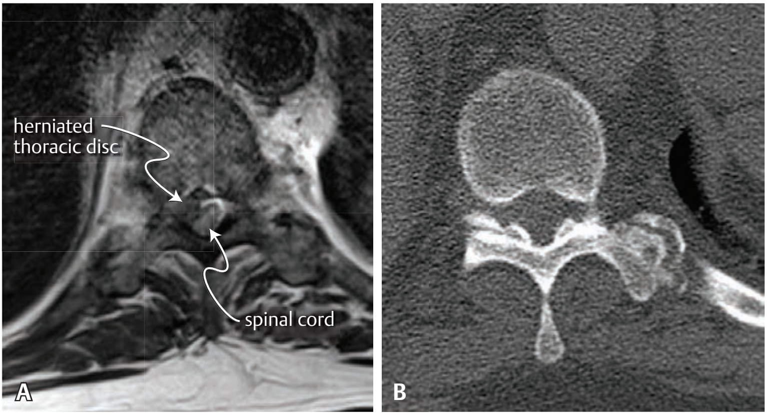

Fig. 76.1 "Soft" herniated thoracic disc. T10–11 right-sided.
Image: A: sagittal T2 MRI. B: CT scan through this disc shows it is not calcified (compare to ▶ Fig. 76.2).

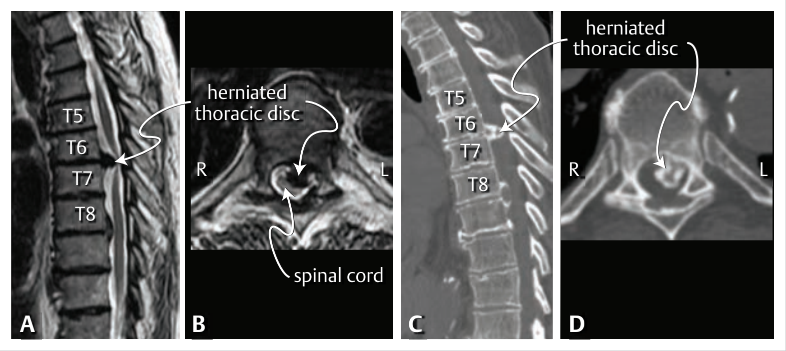

Fig. 76.2 Calcified herniated thoracic disc. T6–7 left-sided.
Image: A & B: T2 MRI (sagittal & axial respectively). C & D: unenhanced (bone window) CT (sagittal & axial respectively) showing the disc is calcified. All images from the same patient.

76.3 Indications for surgery

Herniated thoracic discs requiring surgery are rare.[2] Indications: refractory pain (usually radicular, bandlike) or progressive myelopathy. Uncommon: symptomatic syringomyelia originating at level of disc herniation.

76.4 Surgical approaches

Surgery for thoracic disc disease is challenging because of: the difficulty of anterior approaches, the proportionately tighter space between cord and canal compared to the cervical and lumbar regions, and the watershed blood supply which creates a significant risk of cord injury with attempts to manipulate the cord when trying to work anteriorly to it from a posterior approach. Herniated thoracic discs are calcified in 65% of patients considered for surgery[2] (more difficult to remove from a posterior or lateral approach than non-calcified discs).

Open surgical approaches[2,3]:

1. posterior (midline laminectomy): primary indication is for decompression of posteriorly situated intracanalicular pathology (e.g., metastatic tumor) especially over multiple levels. There is a high failure and complication rate when used for single-level anterior pathology (e.g., midline disc herniation)
2. posterolateral
   a) lateral gutter: laminectomy plus removal of pedicle
   b) transpedicular approach[4]
   c) costotransversectomy (see below)
   d) transfacet pedicle sparing
3. anterolateral (transthoracic): usually through the pleural space
4. lateral extracavitary (retrocoelomic)[5]: an approach posterior (external) to the pleural space

Thoracoscopic surgery is an alternative to open surgery.

76

76.5 Choosing the approach

76.5.1 General information

See anterior approaches to the thoracic spine (p. 1790).

Intraoperative SSEPs and MEPs may be helpful for patients with myelopathy.

For a laterally located herniated noncalcified thoracic disc (e.g., see ▶ Fig. 76.1) posterolateral approach with medial facetectomy is technically simple, and has generally good results. For a central disc herniation, especially when calcified (and therefore not as likely to be able to be pulled out from the side), or when myelopathy is present: transthoracic approach has the lowest incidence of cord injury with the best operative results (▶ Table 76.1).

Table 76.1 Results with various approaches for thoracic spine pathology[6]

Approach	Indication	Total no.	Outcome			
			Normal	Improved	Same	Worse
laminectomy	posteriorly located tumor	129	15%	42%	11%	32%
posterolateral (transpedicular)	radicular pain with lateral disc herniation; biopsy of tumor	27	37%	45%	11%	7%
lateral (costotransversectomy)	fair for midline disc; good ipsilateral access, poor access to opposite side	43	35%	53%	12%	0
transthoracic	best for midline lesions, especially for reaching both sides of cord	12	67%	33%	0	0

For centrally located anterior access: a transthoracic or lateral approach gives the best access. Some prefer a left-sided approach to avoid the vena cava, others prefer a right-sided approach because the heart does not impede access.

76.5.2 Costotransversectomy

Indications: in the past this was often used to drain tuberculous spine abscess. It may be used for lateral disc herniation, biopsy of VB or pedicle, limited unilateral decompression of spinal cord from tumor or bone fragments, or sympathectomy. Can be used at ≈ any T-spine level. Limitations: difficult to visualize anterior canal to access midline anterior pathology. Better for soft disc than for calcified central disc.

Involves resection of the transverse process and at least ≈ 4–5 cm of the posterior rib. A serious risk of this approach is interruption of a significant radicular artery which may compromise spinal cord blood supply; see Spinal cord vasculature (p. 87). There is also a risk of pneumothorax, which is less grave.

Booking the case: Costotransversectomy

Also see defaults & disclaimers (p. 25).

1. position: prone, usually on chest rolls
2. equipment:
   a) microscope (not used for all cases)
   b) C-arm
3. implants: if post-op instability is anticipated, thoracic pedicle screws and possibly a cage (e.g., for fracture or tumor, not typically for disc herniation)
4. neuromonitoring: SSEP/MEP
5. blood availability: type and cross 2 U PRBC
6. consent (in lay terms for the patient—not all-inclusive):
   a) procedure: surgery through the back of the chest to remove a small piece of rib to permit removal of the herniated/calcified disc
   b) alternatives: nonsurgical management, surgery from the side through the chest
   c) complications: spinal cord injury with paralysis, lung complications including pneumothorax or hemothorax (blood or air outside lungs), possible seizures with MEPs

76.6 Surgical technique

The approach can be somewhat difficult due to the infrequent encounter with the anatomy by most neurosurgeons. Be prepared for a “deep, red hole, where everything initially looks the same and the bony anatomy is not easy to define.” With patience and persistence and the help of an anatomic model in the O.R., the surgeon can get his/her bearings. One of the most helpful landmarks is following the NVB (or just the nerve root) medially to the neural foramen.

In the O.R., before the prep and skin incision, localizing X-rays are obtained; a spinal needle inserted between 2 spinous processes may be used as a marker.

Patient position: the approach is from the side of the pathology/symptoms; for central disc herniations a right-sided approach reduces risk of injury to artery of Adamkiewicz (located on the left in 80% (p. 87)). Options:

1. lateral oblique, ≈ 30° elevated from straight prone, a "bean-bag" is good for stabilization. For a thin patient, the surgeon may stand in *front* of the patient (gives more horizontal angle of view—does not work as well with heavier patients due to mass of skin/muscle in the way laterally)
2. prone on chest rolls: the chest roll on the side of the pathology should be more medial to allow the shoulder and scapula to fall forward out of the way

Skin incision options:

1. curved paramedian skin incision: apex oriented away from the midline along the slight depression demarcating the junction of the lateral border of the paraspinal muscles with the ribs (≈ 6–7 cm lateral to midline) centered over the interspace of interest extending ≈ 3 vertebral bodies (VB) above and below. The incision is carried through the skin, subcutaneous fat, trapezius, and (for lower 6 thoracic levels, where most thoracic disc herniations occur) the latissimus dorsi, down to the ribs, and this musculocutaneous flap can be reflected medially as a unit
2. midline incision: need to extend 3–4 levels above and below the level of pathology to get an angle low enough to visualize posterior to the facet in order to access the posterior vertebral body. The inferior aspect can be curved laterally towards the side of pathology. Advantage: a laminectomy can more easily be performed if needed (if the angle does not provide adequate visualization, as a "bail-out" contingency, a facetectomy may be performed, and pedicle may even be removed to access inferior to the disc space. This usually permits easy decompression of the entire thecal sac. In the thoracic spine, stabilization is optional, and if chosen, unilateral pedicle screws and fusion are usually adequate)

Rib removal and thoracic exposure: for a simple biopsy or drainage of a small abscess, removal of only 1 rib may suffice. ★ The rib to be removed is from the level ***inferior*** to the disc space to be accessed[7] (e.g., remove the T5 rib to access T4–5 disc space). For most other pathologies, 2 or 3 ribs are often removed.[8] To access a VB, the like-numbered rib ***and*** the rib below are removed.

There are a number of ligaments attached to the rib: the intercostal neurovascular bundle (NVB) courses medial to the superior costotransverse ligament, which extends from the superior aspect of the rib to the transverse process of the level above. This ligament and the lateral costotransverse ligament are divided and the transverse process is rongeured off (the base of which lies on the lamina directly posterior to the pedicle). This exposes the rib anterior to the transverse process. The periosteum is incised on the rib from the angle of the rib to the costovertebral articulation, and by subperiosteal dissection around its circumference the pleura is dissected off the anterior surface of the rib. The NVB is dissected from the deep-inferior surface along with the periosteum. The rib is then transected laterally at the angle (≈ 5 cm lateral to the rib head) with rib shears, it is gripped with a clamp, and is rotated while the ligaments (including the radiate ligaments which attach the rib to both the VB above and the VB below the disc space at the superior and inferior costal facet, respectively, except T1, 11, & 12 which only articulate with their like-numbered VB) are ***sharply*** dissected off the rib which is then removed. The removed rib material may be used for fusion substrate except in cases of tumor or infection. The pleura is then dissected from the deep surface of the adjacent ribs and VB (taking care not to injure the segmental vessels and to dissect the sympathetic trunk off the VB with the pleura). The pleura is then retracted laterally with a malleable ribbon or Deaver retractor.

The intervertebral foramen of interest may be located by following the NVB of the rib *above* proximally, the intercostal nerve (the ventral ramus of the nerve root at that level) enters between the two pedicles. The dura may then be exposed by enlarging the neural foramen by removing part of the pedicles with a high-speed drill and Kerrison rongeurs.

Instrumentation/fusion are rarely required for simple discectomy. Instability due to fracture, tumor, or extensive resection (e.g., with total facet takedown) necessitates surgical stabilization, typically with pedicle screws/rods extending 2 levels above and 2 levels below. Prior to closure, check for air leak by filling the opening with saline and having the anesthesiologist apply a Valsalva maneuver. If an air leak is identified, a Cook catheter may be placed into the pleural space through the surgical exposure, or alternatively a chest tube is placed through a separate intercostal incision after the laminectomy wound is closed. A post-op CXR is obtained regardless of whether an air leak is identified.

76.6.1 Transpedicular approach

Drilling down the pedicle and removing a small amount of bone from the vertebral body, then pushing material from the epidural space into the defect created and removing it. Requires removal of just the rib head. Advantages: minimal risk of pneumothorax, more familiar anatomy. Disadvantages: requires instrumentation, especially if done bilaterally; the angle is not very oblique so visualization of epidural space is minimal; may need to be done bilaterally if there are extensive bilateral components to the pathology.

Booking the case: Transpedicular approach

Same as for costotransversectomy (p. 1273).

76.6.2 Transthoracic approach

Indications: thoracic disc disease with central fragment or calcified disc, burst fractures of the thoracic spine, etc.

Advantages[9]:
- excellent anterior exposure (especially advantageous for multiple levels)
- little compromise of stability (due to supporting effect of rib cage)
- low risk of mechanical cord injury

Disadvantages:
- requires thoracic surgeon (or familiarity with thoracic surgery)
- some risk of vascular cord injury (due to sacrifice of intercostal arteries)
- definitive diagnosis may not be possible if it is uncertain prior to procedure

Possible complications:
- pulmonary complications: pleural effusion, atelectasis, pneumonia, empyema, hypoventilation
- CSF-pleural fistula

Booking the case: Transthoracic spine surgery

Also see defaults & disclaimers (p. 25).

1. position: typically on the side, often on a beanbag
2. equipment:
   a) microscope (not used for all cases)
   b) C-arm
3. anesthesia: double lumen tube
4. implants: if post-op instability is anticipated, thoracic pedicle screws and possibly a cage (e.g., for fracture or tumor, not typically for disc herniation)
5. neuromonitoring: SSEP/MEP
6. blood availability: type and cross 2 U PRBC
7. some surgeons use chest surgeon for the approach, closure, and follow-up
8. consent (in lay terms for the patient—not all-inclusive):
   a) procedure: surgery through the chest with removal of a small piece of rib to permit removal of the herniated/calcified disc
   b) alternatives: nonsurgical management, surgery from the side or through the back
   c) complications: spinal cord injury with paralysis, pneumothorax, possible seizures with MEPs

76.6.3 Key technical points

1. the services of an experienced thoracic surgeon are usually engaged

2. position: true lateral (facilitates intra-op localizing X-rays); approached from the more involved side. For the upper thoracic *midline* region, some prefer right-side-up to eliminate thoracic aorta from obstructing exposure and to reduce the possibility of encountering the artery of Adamkiewicz,[10] while others prefer left-side-up to use the aorta as a landmark[9] (for levels below the cardiophrenic angle, a left-sided approach is preferred because the inferior vena cava is difficult to mobilize)
3. usually one rib is resected; most often the rib of the vertebra immediately *above* the disc space desired (facilitates exposure). Multiple ribs may be resected to increase exposure
4. when removing the vertebral body (VB) (corpectomy, e.g., for osteomyelitis, especially Pott's disease or for kyphoscoliosis)
   a) the posterior cortex of the VB must be pulled anteriorly (e.g., with angled curettes) to avoid mechanical cord trauma
   b) anterior fusion may be performed using the removed rib. If inadequate, fibula or iliac crest may be used
5. sizeable radicular arteries are spared. The intercostal nerve is used as a guide to the intervertebral foramen (nerve enters foramen superiorly and posteriorly)
6. the disc space is situated off the caudal aspect of the intervertebral foramen for most thoracic levels
7. one or two intervertebral arteries and veins usually have to be sacrificed; to minimize the risk of ischemic cord injury, cut them as close to the midline of the spine as possible (collaterals tend to lie on the lateral aspect of the spine)
8. the sympathetic chain is dissected off the VBs and is pushed posteriorly

76.6.4 Lateral retropleural approach

See reference.[5]

General information

An extra-coelomic approach does not violate the pleural space. If the parietal pleura is entered the procedure is essentially the same, but is considered a "trans-thoracic" approach.

Check a pre-op MRI or CT for the location of the aorta and to rule out aortic aneurysm which is a relative contraindication. For a herniated thoracic disc, a pre-op CT is necessay to determine if the disc is calcified (see ▶ Fig. 76.2), which alters the technique.

A dual lumen endotracheal tube is *not* required.

Indications

- thoracic corpectomy/discectomy. For herniated disc, this approach is indicated for a central disc herniation, or a calcified herniated disc that is situated anterior to the spinal cord. Pre-op CT is mandatory (see above)
- for some lateral interbody fusions (e.g., LLIF) at L1–2 and occasionally even at L2–3 if the ribs substantially overlie the disc space

Applied anatomy

External oblique (EO) muscle (mnemonic for direction of fibers: "hands in pocket" directed medially and inferiorly). The endothoracic fascia (ETF) can be dissected from the internal surface of the rib to allow the rib to be removed. Then the space between the ETF and the parietal pleura is entered (not the potential pleural space between the parietal and visceral pleura) to perform the operation. If the parietal pleura is violated during the approach, this can produce a pneumothorax. If the visceral pleura is also perforated, this can produce an air leak in addition to the pneumothorax.

Equipment

The same retractor (e.g., the Maxcess™ retractor by Nuvasive) used for lateral lumbar interbody fusion (p. 1802) may be used with blade extenders and an "egg beater" (lung retractor) center blade to retract the lungs. The retractor is "reversed" so that the center blade is positioned *anteriorly* and the table adapter arm is connected to the posterior "poker chip" on the retractor so that when the retractor is expanded in the AP direction, the lung retractor blade moves anteriorly and the lateral blades stay stationary.

The following additional instruments are needed:

- endo-Kitners (Kitners at the end of a "stick")

- Doyen rib separators
- Alexander periosteal elevator or Pennfield #1 dissector
- rib shears
- extra long instruments, including: e.g., long Midas Rex drill (21 cm attachment: 21TU with 21MH30 dissecting tool) or an angled drill (e.g., Midas Rex Clear View™) with diamond burr, and/ or BoneScalpel (with round tip), long suctions, Kerrison rongeurs…
- Intraoperative electrophysiologic spinal cord monitoring is usually used (typically SSEP & MEP).

Positioning and marking

The side of the approach is determined by the laterality of the disc herniation. If it is exactly midline, a left-sided approach is often preferrable because it is easier to retract the aorta than the vena cava.

Fluoro is used to position the patient in a true lateral position with the spinous processes midway between the pedicles at the surgical level and the patient is stabilized with adhesive tape.

A cross-hair localizer is used with fluoro to mark the skin at the anterior and posterior extent of the disc of interest. Mark the skin incision starting from the midposition of the disc and extending posteriorly along the direction of the ribs for 6–7 cm (by going a little more posterior than a perfectly lateral approach, the working distance is shortened and the angle is a little easier). Above ≈ T6 the scapula begins to get in the way, and it may need to be released a little by splitting the fibers of the latissiums dorsi.

Incision and approach

Make the skin incision along the surface of the rib overlying the disc space. The actual number of this rib is usually not important but it is typically 2 levels above the disc space in question (e.g., the T9 rib will be resected in approaching T10–11). Incise the external oblique (EO) over the center of the rib, and use a curette (e.g., Penfield #1 or Alexander) to separate the bone of the rib from the endothoracic fascia (ETF) deep to the rib. Sweeping a Doyen rib dissector beneath the rib can help complete the separation. Remove a section of the rib using rib shears (about 6 cm, get as far posterior as you can).

Separating the ETF from the outer surface of the parietal pleura (to enter the space between the ETF and the parietal pleura): during the process of separating the rib from the ETF, there is often an iatrogenically created opening through the ETF where this space can be entered (if not, carefully create an opening without violating the parietal pleura). Develop this potential space: begin to enlarge it using Kitners (some prefer endo-Kitners) and carefully insinuate a finger (moistening the glove helps) into this space after rib removal. If your finger moves freely, you have probably penetrated the parietal pleura and entered the pleural space (between the parietal and visceral pleura). In some cases it is not possible to develop this plane, in this case the pleural space is utilized, which works nearly as well (except at the diaphragm). Work the pleura and lung and (for lower T-spine) diaphragm anteriorly. Use a hand-held egg-beater retractor & follow the plane down to lateral VB, a sponge stick may help. Place the Maxcess retractor fitted with extensions oriented with the handles toward the abdomen with a short blade in the middle position for starters. Then replace it with an egg-beater blade. Connect the adapter arm to the “poker chip” furthest away from the posterior blade (so that posterior blade moves and not the side blades as you open the retractor). Take segmental artery(ies) as soon as they are seen (these usually cross in the middle of the VB).

Corpectomy

For a corpectomy, position blades of the retractor to span endplate to endplate (across the VB to be removed). Dissect the sympathetic chain anteriorly off the lateral VBs. If a segmental artery overlies the VB to be removed, it is coagulated and divided.

Discectomy for herniated thoracic disc

See reference.[11]

The head of the rib of the vertebral body below the the disc space overlies the posterior disc space (► Fig. 76.3) and must be removed (this is usually a different rib than the one from which the lateral part was removed earlier to access the retropleural space).

Once the rib head is removed, locate the pedicle of the lower VB. The disc space is just cranial to the pedicle. Locate the intervertebral (neural) foramen—the disc space is situated at the caudal aspect of the foramen. For herniated disc or other access to spinal canal/dura: you need to enlarge the neural foramen to be able to work, by drilling the cranial aspect of the pedicle of the level BELOW the disc space. If the pathology extends significantly posteriorly it may be necessary to remove part or all of the facet joint.

Fig. 76.3 Surgical view of lateral thoracic vertebral bodies from a left-sided approach (surgeon standing in back of the patient). A: anatomy. B: appearance after removal of rib head to access the T8–9 disc space.
Dashed lines depict bone that is removed (e.g., with a drill) for excision of a calcified thoracic disc (see ▶ Fig. 76.4 for post-op CT appearance).
Abbreviations: tp = transverse process; sp = spinous process; vb = vertebral body; PLL = posterior longitudinal ligament.

To remove a calcified thoracic disc, use e.g., the Midas Rex with 21 TU bit or Clear View™ diamond tip or the Misonix bone scalpel with the round burr to drill away bone from the posterior vertebral bodies above and a little below the disc space to a depth that is even with the medial aspect of the contralateral pedicle to expose the anterior spinal canal (▶ Fig. 76.4) and dura. Then hollow out the calcified disc with the drill until it is egg-shelled. Use a straight curette to push the egg-shell away from the dura into the defect now created in the vertebral bodies from whence it can then be removed.

Closure and drains

An air leak may occur if the visceral pleura (lung lining) is violated. To rule this out, fill the wound with irrigation and have the anesthesiologist apply a Valsalva maneuver. Continuous bubbling (as opposed to initial bubbling that stops) signifies an air leak. In this case, if the leak is small, a medium hemovac in the pleural space may suffice; for large air leaks an actual chest tube is recommended and is connected to suction through a water seal.

If the parietal pleura (chest wall lining) alone is violated, an air leak will not result but a pneumothorax can occur. A medium hemovac or a pigtail catheter is usually adequate to treat this. Alternatively, a red-rubber catheter may be placed outside the parietal pleura, and the muscle closed around it. A Valsalva maneuver is performed by the anesthesiologist while the distal tip of the red rubber catheter is placed in water. As the lung expands a limited amount of bubbles will occur as the air is expelled from the pleural space (continuous bubbling means an air leak and requires a chest tube or equivalent). The red rubber catheter is then pulled out and a final stitch can be placed if necessary. Then the Valsalva can be released.

77 Cervical Disc Herniation

77.1 Cervical disc herniation – general information

Important applied anatomy in herniated cervical disc (HCD):

1. in the cervical region, the nerve root exits *above* the pedicle of its like-numbered vertebra (opposite to the situation in the lumbar spine, due to the fact that there are 8 cervical nerve roots and only 7 cervical vertebrae)
2. as each nerve root exits through its neural foramen, it passes in close relation to the undersurface of the like-numbered pedicle
3. the intervertebral disc space is located close to the inferior portion of the pedicle (unlike the lumbar region)

77.2 Cervical nerve root syndromes (cervical radiculopathy)

77.2.1 General information

Due to the facts listed above, an HCD usually impinges on the nerve exiting from the neural foramen *at* the level of the herniation (e.g., a C6–7 HCD usually causes C7 radiculopathy). This gives rise to the characteristic cervical nerve root syndromes shown in ▶ Table 77.1.

Table 77.1 Cervical disc syndromes

	Level of herniated cervical disc			
	C4–5	**C5–6**	**C6–7**	**C7–1**
% of cervical discs	2%	19%	69%	10%
compressed root	C5	C6	C7	C8
reflex diminished	deltoid & pectoralis	biceps & brachioradialis	triceps	finger-jerk[a]
motor weakness	deltoid	forearm flexion	forearm ext (wrist drop)	hand intrinsics
paresthesia & hypesthesia	shoulder	upper arm, thumb, radial forearm	fingers 2 & 3, all fingertips	fingers 4 & 5

[a] not everyone has a finger flexor reflex. Description: gently lift the fingertips of the patient’s pronated hand and tap the underside of the fingers with a reflex hammer. When present, fingers flex in response

77.2.2 Miscellaneous clinical facts

C4 radiculopathy is not common, and may produce nonradiating axial neck pain.

Left C6 radiculopathy (e.g., from C5–6 HCD) occasionally presents with pain simulating an MI (pseudo-angina).

C8 and T1 nerve root involvement may produce a partial Horner syndrome.

The most common scenario for patients with herniated cervical disc is that the symptoms were present upon awakening in the morning, without identifiable trauma or stress.[1]

Patients may offer (or may need to be asked) that placing the ipsilateral hand or forearm on the top of the head sometimes gives relief of pain due to a herniated cervical disc (so-called “cervical hand sign,” ▶ Fig. 77.1).

77.3 Cervical myelopathy and SCI due to cervical disc herniation

Acute cord compression presenting with myelopathy or spinal cord injury (SCI) (including complete SCI and incomplete syndromes, especially **central cord syndrome** (p. 1132) and sometimes Brown-Séquard syndrome (p. 1135) [2]) is well described in association with traumatic cervical disc herniation.[3] Less commonly, these findings may occur in non-traumatic cervical disc herniation.

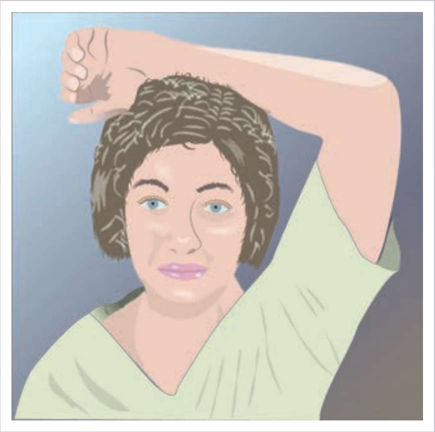

Fig. 77.1 "Cervical hand sign." A position that may provide some relief to patients with radiculopathy from cervical disc herniation.

77.4 Differential diagnosis

See Differential diagnosis (p. 1710).

77.5 Physical exam for cervical disc herniation

77.5.1 Overview

1. evaluation for radiculopathy
   a) lower motor neuron findings
      - weakness usually in one myotome group on one side
      - muscle bulk and tone: atrophy and fasciculations may be present
   b) sensation: with nerve root compression, sensory loss will follow a dermatomal pattern and will be in the same nerve root distribution as the weakness
   c) muscle stretch reflexes
   d) mechanical signs: reproduction of radicular symptoms with axial loading of the head
2. evidence of spinal cord involvement (myelopathy)
   a) upper motor neuron findings, usually in the lower extremities
      - weakness may occur without atrophy or fasciculations
      - spasticity: poor control of the legs when walking, scissoring of the legs
   b) sensation: any loss below the level of involvement will follow spinal cord patterns
      - complete loss
      - Brown-Séquard syndrome (p. 1135) pattern: ipsilateral vibratory and position sense loss and contralateral loss of pinprick
      - central cord syndrome: suspended sensory loss in upper extremities, less impaired below
      - pathologic reflexes: Hoffmann's reflex, Babinski sign, ankle clonus

77.5.2 Signs useful in evaluating cervical radiculopathy

General information

Almost all herniated cervical discs cause painful limitation of neck motion. Neck *extension* usually aggravates pain when cervical disc disease is present (a minority of patients instead exhibit pain with flexion). Some patients find relief in elevating the arm and cupping the back or the top of the head with the hand (abduction relief sign, see below for shoulder abduction test). Lhermitte's sign (p. 1712) (electrical shock-like sensation radiating down the spine) may be present; see DDx (p. 1712).

Miscellaneous

The following tests were found to be specific, but not particularly sensitive in detecting cervical root compression[4]:

1. Spurling's sign[5]: radicular pain reproduced when the examiner exerts downward pressure on vertex while tilting head towards symptomatic side (sometimes adding neck *extension*). Causes narrowing of the intervertebral foramen and possibly increases disc bulge. Used as a "mechanical sign" analogous to SLR for lumbar disc herniation
2. axial manual traction: 10–15 kg of axial traction is applied to a supine patient with radicular symptoms (pull up on patient's mandible and occiput). The reduction or disappearance of radicular symptoms is a positive finding
3. shoulder abduction test[6]: a sitting patient with radicular symptoms lifts their hand above their head. The reduction or disappearance of radicular symptoms is a positive finding. Moderately sensitive, fairly specific[7]

77.6 Radiologic evaluation

77.6.1 MRI

The study of choice for initial evaluation for herniated cervical disc (HCD) and for imaging the spinal cord.

Protocol:

1. sagittal T1WI
2. multiple echo cardiac gated sagittal images (Tr = 1560, Te = 25, 4th echo)
3. T2* GRE image: dark material adjacent to disc space is bone, disc is higher signal, CSF and flowing blood are high signal.

77.6.2 CT and myelogram/CT

Indications: when MRI cannot be done or when more bony detail than what MRI provides is required. Evaluates for ossification of the posterior longitudinal ligament (OPLL) when suspected.

Plain CT: is usually good at C5–6, is variable at C6–7 (due to artifact from patient's shoulders, depending on body habitus), and is usually poor at C7–1.

Myelogram/CT (water-soluble intrathecal contrast): invasive, on rare occasions requires overnight hospitalization. Accuracy is ≈ 98% for cervical disc disease.

77.6.3 Electrodiagnostics (EMG and NCV)

Compression may occur at the level of the dorsal (pre-ganglionic) sensory root (which, if occurs alone, produces a sensory-only radiculopathy) and/or at the ventral (motor) root. When motor exam is normal, EMG is unlikely to show abnormality. The AANEM practice parameter for cervical radiculopathy[8,9,10] reports sensitivity of 50–71% for the needle EMG examination and correlation between positive needle EMG and radiologic findings of 65–85%.

EMG can also be normal in sensory-only radiculopathy, which occasionally occurs in cervical spine, but not in lumbar spine. Since most muscles have at least dual innervation this poses a particular challenge for proximal cervical radiculopathies in which many muscles have the same shared innervation, e.g., biceps, deltoid, brachioradialis, infraspinatus, and supraspinatus are all innervated by C5–6.

For both cervical and lumbosacral radiculopathy, screening 6 muscles representing all root levels to include paraspinal muscles yields consistently high identification rates.[11]

For muscles to demonstrate fibrillations and positive waves there must be axonal loss in the motor nerve axons which innervate a muscle. Muscle demonstrates fibs and positive waves within 1 to 2 weeks following loss of innervation depending on the distance from the nerve to the muscle.

NCV is helpful when assessing for peripheral neuropathies, which may have symptoms similar to radiculopathy (e.g., carpal tunnel syndrome vs. C6 radiculopathy; ulnar neuropathy vs. C8 radiculopathy). A good physical exam can differentiate these entities in most cases.

Practice guideline: EDX guidelines for cervical radiculopathy[10]

1. Guideline: EMG needle examination:
   a) needle examination of at least 1 muscle innervated by C5, C6, C7, C8, and T1 spinal roots in a symptomatic limb
   b) cervical paraspinal muscles at 1 or more levels (except in patients with prior posterior approach cervical surgery)
   c) if abnormalities are identified, perform studies of 1 or 2 additional muscles innervated by the suspected root and different peripheral nerve
2. Guideline: At least 1 motor and 1 sensory nerve conduction study (NCS) in the clinically involved limb to determine if there is concomitant polyneuropathy or nerve entrapment. Motor and sensory NCS of median and ulnar nerves if symptoms and signs suggest CTS or ulnar neuropathy. If 1 or more NCS are abnormal or if clinical features suggest polyneuropathy, further evaluation may include NCS of other nerves in the ipsilateral and contralateral limb

77.7 Treatment

77.7.1 General information

Over 90% of patients with acute cervical radiculopathy due to cervical disc herniation can improve without surgery,[12] and regression of an extruded cervical disc has been demonstrated radiographically by CT and MRI.[13,14,15] The recovery period may be made more tolerable by adequate pain medication, anti-inflammatory medication (NSAIDs or short-course tapering steroids), and intermittent cervical traction (e.g., gradually escalating up to 10–15 lbs for 10–15 minutes, 2–3 × daily).

Surgery is indicated for those that fail to improve or those with progressive neurologic deficit while undergoing non-surgical management.

Management of myelopathy/central cord syndrome associated with acute cervical disc herniation is controversial, since the natural history is favorable in most cases. However, some patients have poor recovery and experience permanent deficits even with emergency surgery.[16]

77.7.2 Conservative management

Modalities include:

1. physical therapy, which may also include cervical traction
2. interventional pain management
   a) trigger point injections
   b) facet blocks
   c) epidural steroid injection: not used as often and with lumbar spine

77.7.3 Surgery

Surgical options

1. anterior cervical discectomy: see below
   a) without any prosthesis or fusion: rarely used today
   b) combined with interbody fusion: the most common approach
      - without anterior cervical plating
      - with anterior cervical plating or with zero profile
   c) with artificial disc AKA cervical disc arthroplasty
2. posterior approaches
   a) cervical laminectomy: not typically used for a herniated cervical disc, more common for cervical spinal stenosis, OPLL
      - without posterior fusion
      - with lateral mass fusion
   b) keyhole laminotomy: sometimes permits removal of disc fragment

For practice guidelines regarding intra-op electrophysiologic, see monitoring for surgery for cervical radiculopathy (p. 1304).

Anterior cervical discectomy with fusion (ACDF)

Without special modifications, a routine anterior approach is usually able to access levels C3–7. In patients with short thick necks, access may be even more limited. In some cases, with long thin necks, up to C2–3 or as low as C7–1 can be approached anteriorly.

Advantages over posterior (nonfused) approach:

1. safe removal of anterior osteophytes
2. fusion of disc space affords immobility (up to 10% incidence of subluxation with extensive posterior approach)
3. only viable means of directly dealing with centrally herniated disc

Disadvantages over posterior approach: immobility at fused level may increase stress on adjacent disc spaces. If a fusion is performed, some surgeons prescribe a rigid collar (e.g., Philadelphia collar) for 6–12 weeks. Multiple level ACDF can devascularize the vertebral body (or bodies) between discectomies.

Booking the case: ACDF

Also see defaults & disclaimers (p. 25).

1. position: supine, some use halter traction with this
2. equipment:
   a) microscope (not used by all surgeons)
   b) C-arm
3. implants: graft (e.g., PEEK, cadaver bone, titanium cage…) and anterior cervical plate (optional, especially on single level ACDF)
4. neuromonitoring: (optional) some surgeons use SSEP/MEP
5. consent (in lay terms for the patient—not all-inclusive):
   a) procedure: surgery through the front of the neck to remove the degenerated disc and bone spurs, and to place a graft where the disc was, and possibly place a metal plate on the front of the spine. Some surgeons take bone from the hip to replace the removed disc
   b) alternatives: nonsurgical management, surgery from the back of the neck, artificial disc (in some cases)
   c) complications: swallowing difficulties are common but usually resolve, hoarseness of the voice (< 4% chance of it being permanent), injury to: foodpipe (esophagus), windpipe (trachea), arteries to the brain (carotid), spinal cord with paralysis, nerve root with paralysis, possible seizures with MEPs

Technique

A summary of the steps: a 4–5 cm horizontal skin incision oriented along Langer's lines is centered on the anterior margin of the SCM in the mediolateral plane. Fluoroscopy is used for cranio-caudal localization, for C5–6 it is usually at the level of the cricoid cartilage. Many right-handed surgeons prefer operating from the right side of the neck, although the risk to the recurrent laryngeal nerve (RLN) is possibly lower with a left-sided approach (the RLN lies in a groove between the esophagus and trachea). The skin may be undermined off the platysma to permit a vertical incision in the platysma in the same orientation as its muscle fibers. Most just incise the platysma horizontally with Metzenbaum scissors.

Dissect in tissue plane medial to SCM. Sweep the omohyoid medially (to stay out of it and to protect the RLN). The trachea + esophagus are retracted medially. The carotid sheath + SCM are retracted laterally.

Verify the level with lateral C-spine X-ray with bayonetted spinal needle in the interspace. Bipolar cautery is used on the prevertebral fascia and medial edges of the longus colli muscles longitudinally in the midline. Self-retaining retractor blades are inserted underneath the fascia to retract the longus colli muscles laterally. The anesthesiologist deflates the cuff on the endotracheal tube and then re-inflates it using minimal leak technique to reduce the risk of compression injury from the retractor. The disc space is incised with a 15 scalpel blade. The discectomy is performed with curettes and pituitary rongeurs; a vertebral body spreader or Caspar pin distractor aids the exposure. The posterior longitudinal ligament (PLL) is opened, typically by insinuating a nerve hook through the fibers, and then expanding this opening initially with a 1 mm Kerrison rongeur and then with 2 mm Kerrison rongeurs. The subligamentous space is probed with a blunt nerve hook. The posterior osteophytes of the VB above and below are removed with a 2 mm Kerrison rongeur. Decompression of the roots is verified with the blunt nerve hook. A fusion is usually performed at this time by placing a graft in the interspace.

For redo operations (same or different levels): approach is usually from the same side as previous operation(s) since many patients have swallowing issues from the previous operation, and some may be due to partial recurrent laryngeal nerve injury, which can be subclinical and could result in a permanent need for a feeding tube if a contralateral injury occurs. If for some reason it is desired to go to the opposite side, an evaluation by an ENT physician is recommended, and should include scoping the patient to rule out subclinical vocal cord problems that could turn into major difficulties if bilateral.

Choice of graft material

Autologous bone (usually from iliac crest), non-autologous bone (cadaveric), bone substitutes (e.g., hydroxylapatite[17]) or synthetics (e.g., PEEK or titanium cage) filled with osteogenic material. Substitutes for autologous bone eliminate problems with the donor site (p. 1287), but may have a higher rate of absorption. There were cases of HIV transmission from cadaveric bone grafts in 1985; however, as a result of significant improvements in antibody testing and careful screening of donors, no further cases have been reported.

Anterior cervical plating

Recommendations for plating following ACDF are shown in **Practice guideline: Anterior cervical plating** (p. 1285).

Practice guideline: Anterior cervical plating

1-level ACDF: The addition of an anterior plate to an ACDF is recommended to reduce the pseudarthrosis rate and graft problems (Level D Class III) and to maintain lordosis (Level C Class II), but it does not improve clinical outcome alone (Level B Class II).[18]

2-level ACDF: Plating is recommended to improve arm pain. Plating does not improve other outcome parameters (Level C Class II).[18]

Use of bone morphogenetic proteins (BMP)

Practice guideline: Use of BMP in cervical interbody grafting

Current evidence does not support the *routine* use of rhBMP-2 for cervical arthrodesis (Level C Class II)[19] [italics added].

Note: Use with precautions (see text); may be indicated in cases with high risk of nonunion.

Use of BMP in anterior cervical discectomies is not FDA approved, but has been used off-label. Complication rates as high as 23–27% have been reported (including post-op swallowing or respiratory difficulties as a result of edema which is usually temporary) compared to 3% without BMP.[19] If used, it is recommended that a smaller dose be employed than in the lumbar spine (25% has been advocated) and to avoid contact of BMP with soft tissues in the neck.

Post-op check

In addition to routine, the following should be checked

1. evidence of airway obstruction—post-op wound hematoma: should be first consideration. Wound may need to be emergently opened at bedside (before getting to the OR) if airway is

compromised, see **Carotid endarterectomy,** disruption of arteriotomy closure, management (p. 1568). Also consider swelling from IJV thrombosis (rare) in differential diagnosis (see below)

   a) respiratory distress
   b) extreme difficulty swallowing: alternatively may indicate anterior extrusion of bone graft impinging upon esophagus (check lateral C-spine X-ray)
   c) tracheal deviation: may be visible or may be seen on AP C-spine X-ray

2. weakness of nerve root of level operated: e.g., biceps for C5–6, triceps for C6–7
3. long tract signs (Babinski sign…) which may indicate cord compression by spinal epidural hematoma
4. hoarseness: may indicate vocal cord paresis from recurrent laryngeal nerve injury: hold oral feeding until this can be further assessed

ACDF complications

General information

Common complications are listed below, see references[20,21] for more details. The most common complication following ACDFs: swallowing difficulties (p. 1287) (may be multifactorial).

1. exposure injuries
   a) perforation of viscus: minimize risk by blunt retraction until longus colli is separated from its attachment to vertebrae
      - pharynx
      - esophageal perforation (p. 1288): a rare but well-known complication
      - trachea
   b) vocal cord paresis: due to injury of the recurrent laryngeal nerve (RLN) or vagus. Incidence: 11% temporary (84% of temporary palsies resolve clinically by 6 months), 4% permanent paresis. Incidence may be higher in revision surgery. Symptoms include: hoarseness, breathiness, cough, aspiration, mass sensation, dysphagia, and vocal cord fatigue.[22] Avoid sharp dissection in paratracheal muscles. Some cases may be due to prolonged retraction against trachea and not to nerve division; to reduce this risk, after the self-retaining retractor is placed, have the anesthesiologist deflate the cuff on the ET tube and then inflate it to minimal leak pressure. More common with right-sided approaches, primarily in the lower cervical spine (C5–6 and below) where the RLN is more vulnerable[22]
   c) vertebral artery injury: thrombosis or laceration. 0.3% incidence.[21] Treatment alternatives include: packing, direct repair by temporary clipping with aneurysms clips and repair with 8–0 prolene[23] and endovascular trapping. Risks of treating hemorrhagic complications with packing include: recurrent bleeding, AV fistula, pseudoaneurysm, arterial thrombosis,[21] distal embolic stroke (primarily in cerebellum)
   d) carotid injury: thrombosis, occlusion, or laceration (usually by retraction)
   e) CSF fistula: usually difficult to repair directly. Place fascial graft beneath bone plug. Keep HOB elevated post-op. Consider: dural sealant (fibrin glue, DuraSeal®…), lumbar drain
   f) Horner syndrome: sympathetic plexus lies within longus coli, thus do not extend dissection far laterally into these muscles
   g) thoracic duct injury: in exposing lower cervical spine, primarily on left
   h) thrombosis of internal jugular vein[24]: rare. Carries 2–3% risk of PE.[25] Treatment options: anticoagulation (oral or IV) may lower the mortality,[26] SVC filter if anticoagulation is contraindicated,[27] percutaneous thrombectomy[28]
2. spinal cord or nerve root injuries
   a) spinal cord injury: especially risky in myelopathy due to narrowed canal. Minimize risk by penetrating the osteophyte at the lateral margin of interspace (however, this increases risk to nerve root)
   b) avoid hyperextension during intubation: use video laryngoscopy, or second choice, asleep fiberoptic bronchoscopy (awake fiberoptic intubation is rarely used)[29]
   c) bone graft must be shorter than interspace depth. Exercise caution in tapping graft into position
   d) sleep-induced apnea: rare but serious complications of C3–4 level operations.[30] May be associated with bradycardia & cardiorespiratory instability. Possibly due to disruption of the afferent component of the central respiratory control mechanism
3. bone fusion problems
   a) failure of fusion (pseudarthrosis): see below
   b) anterior (kyphotic) angulation deformity: may be as high as 60% with Cloward technique (may be reduced by collar immobilization). May develop in Hirsch technique with excessive bone removal

   c) graft extrusion: 2% incidence (rarely requires reoperation unless compression of cord posteriorly, or esophagus or trachea anteriorly occurs)
   d) donor site complications: hematoma/seroma, infection, fracture of ilium, injury to lateral femoral cutaneous nerve, persistent pain due to scar, bowel perforation
4. miscellaneous
   a) wound infection: incidence < 1%
   b) post-op hematoma: *see above*. Placing cervical collar in O.R. may delay recognition of immediate post-op hematoma
   c) dysphagia and hoarseness: common. Usually transient (*see below*)
   d) adjacent level degeneration: controversial whether this represents a sequela to altered biomechanics from surgery, or a predisposition to cervical spondylosis.[31] Many (≈ 70%) are asymptomatic[32]
   e) postoperative discomfort:
      - globus: the sensation of a lump in throat (see below)
      - nagging discomfort in neck, shoulder, and very commonly in interscapular regions (may last several months). May correlate with amount of distraction of the disc space
   f) complex regional pain syndrome (CRPS) AKA reflex sympathetic dystrophy (**RSD**): rarely described in the literature,[33] possibly due to stellate ganglion injury; see discussion of RSD (p. 525)
   g) angioedema: massive edema of the tongue and neck.[34] A dramatic hypersensitivity reaction (not really a direct complication of ACDF, but superficially can mimic some findings of post-op hematoma). If limited to the tongue, the airway is not compromised. See treatment (p. 233)
   h) pneumothorax or hemothorax[35]: accessing C7–1 or lower may expose the pleural apex

Dysphagia following ACDF

Symptoms: Include: difficulty swallowing (solids, liquids including saliva), pain with swallowing (odynophagia), globus (sensation of a lump in throat), and compromise of ability to protect against aspiration. Food may stick in the throat (or feel as if it is stuck) and there may be coughing or choking.

Incidence: Difficult to accurately quantify since definitions & surgical techniques vary, and selection biases produce wide ranges. Early dysphagia is common, with incidence as high as 60%[36] in a retrospective survey after noninstrumented fusion (dysphagia occurred in 23% in a control group undergoing unrelated lumbar spine surgery[36]), and 50% in a prospective study.[37] At 6 months, only ≈ 5% reported moderate or severe dysphagia.[37] Surgery at multiple levels increased the risk at 1 & 2 months.[37] Dysphagia decreases significantly in most cases by 6 months.[37]

Etiologies: mild cases are usually self-limited and are related to a combination of retraction on esophagus, post-op inflammation, irritation following endotracheal intubation, and presence of hardware. More pronounced or prolonged dysphagia may be due to:

1. post-op hematoma. If severe, may cause tracheal obstruction (see above)
2. post-op edema, due in part to retraction of esophagus
3. effects of general anesthesia: e.g., irritation from ET tube. Accounts for up to 23% of early symptoms (dysphagia occurred in 23% in a control group undergoing unrelated lumbar spine surgery[36]). Usually subsides within ≈ 24–72 hours
4. recurrent laryngeal nerve dysfunction:
   a) temporary: usually due to traction on the nerve
   b) permanent: 1.3% at 12 months[37]
5. esophageal injury
   a) at time of surgery
   b) delayed: possibly from repetitive abrasion on hardware or from unrecognized esophageal injury at time of surgery[38]
6. cervical collar
   a) prevents patient from lowering jaw during swallow phase, which compromises effective glottic closure of airway
   b) may be too tight, thereby directly compressing the throat
7. protrusion of graft/hardware anterior to the vertebral bodies
   a) some protrusion is present with most anterior hardware. This may be minimized with “zero profile” instrumentation
   b) hardware failure (screw pullout, backout or breakage, plate loosening, pullout or migration)
   c) interbody graft migration: without anterior plate, or in conjunction with anterior plate displacement
8. excessive adhesions[39]

9. denervation of the pharyngeal plexus[39]
10. rare conditions: swelling from internal jugular vein (IJV) thrombosis, angioedema

Management:

1. initial management: rule out emergent/serious conditions (severe edema, hematoma with airway compromise, risk of aspiration)
    a) if there is significant stridor or dysphonia, especially if tracheal deviation is obvious, someone must stay with the patient as efforts are made to emergently take the patient to the O.R. for wound exploration & evacuation of hematoma if any. Consider opening the wound at the bedside if delays occur or if symptoms are severe; see Carotid endarterectomy, disruption of arteriotomy closure, management (p. 1568). Emergent anesthesia consultation for airway protection— alert them to the likelihood of deviated trachea, which challenges even the most expert at intubating
2. once emergent conditions are ruled out, early management is geared towards amelioration of symptoms
    a) advise patient to eat softer foods (temporarily avoiding steak or bread), to chew food well, to wash down dry foods with a drink. Reassure patient that most cases largely resolve within 6 months[37]
    b) treatment with dexamethasone 8-10 mg TID for 3 days will get most patients through this
    c) if significant symptoms persist > 2 weeks
        - ENT referral for evaluation that may include: laryngoscopy, FEES (flexible endoscopic evaluation of swallowing), to rule out vocal cord paralysis (from RLN injury (p. 1289)) or other etiologies
        - modified barium swallow (mBS)
3. persistent symptoms may be amenable to surgical intervention, including hardware removal and lysing of adhesions.[39] Management of esophageal perforation usually requires consultation with ENT (see below)

Esophageal perforation after anterior cervical spine surgery

Incidence: Data is imprecise due to reporting bias. It is also likely that minor injuries that heal spontaneously and go unrecognized may occur. Reported range: 0.02% to 1.52%. Incidence is higher when the surgery is performed for trauma.[40] Incidence may be higher with use of anterior cervical plate.

Etiologies: Intraoperative injury (direct injury or from retractor), or delayed (from hardware failure & hardware erosion, graft extrusion…).

Possible sequelae: Dysphagia, local infection, deep infection (including osteomyelitis), pseudarthrosis, pharyngoesophageal diverticulum, sepsis, mediastinitus, death in 4%.[40] Species reported with infection include: *Staphylococcus* (including MRSA), *Candida*, *Pseudomonas*, and *Streptococcus*.

Delay to diagnosis: Mean = 717 days. Median = 44.5 days.[40]

- intraoperative recognized (often heralded by the appearance of mucous appearing in the operative field): zero delay to diagnosis
- early post-op: < 30 days post-op. Most are probably unrecognized intraoperative injuries
- delayed: as late as 18 years. Mostly hardware failure/erosion

Symptoms: Dysphagia (the most common), odynophagia, fever, neck swelling, and wound leakage.[40]

Signs include: Fever, subcutaneous emphysema, sepsis ± shock

Evaluation: Approximately 33% may not be detected on imaging or endoscopy.[41]

- swallow studies:
    - gastrograffin swallow: usually administered by radiologist to look for leak, or
    - (modified) barium swallow: usually curated by speech pathologist, can assess for leaks and also diagnose other swallowing pathologies
- esophagoscopy by ENT
- CT scan: assesses bony fusion (important to know since hardware often has to be removed) and may assist in making diagnosis
- MRI without and with contrast: assesses for epidural abscess, vertebral osteomyelitis (contrast T1WI)
- CXR

Management: Challenging. There is no consensus on optimal management. A multidisciplinary approach with head and neck surgeons together with the spine surgeon,[38] infectious disease specialist and, when needed, a cardiothoracic surgeon is suggested, with the following:

- primary closure: usually effective at the time of the original surgery if perforation is recognized then, or it is diagnosed within 24 hrs of the time of injury.[42] Not recommended once adjacent tissues become involved and/or when esophagus is inflamed (high risk of esophageal stricture)
- closure with muscle flap or possibly a pedicle flap: sternocleidomastoid muscle is most common. Other muscle flaps include: radial forearm, pectoralis, infrahyoid, omohyoid, latissisus dorsi, longus coli. Also described: omentum, jejunum
- removing all anterior hardware increases the chance of success.[40] If there is evidence that the fusion is not solid, posterior instrumentation may be necessary
- a wound drain is placed external to the esophagus, and can be used to check for extravasation of methylene blue administered orally to verify esophageal healing
- esophageal bypass: rarely required, high morbidity
- conservative management: usually used in conjunction with above. Use of conservative management alone is less common and is controversial. May be more viable if used early for small, contained defects (i.e., not involving mediastinitis[43]). Usually includes:
  - putting the esophagus at rest:
    - strict NPO
    - nutrition via one of the following: tube feeding (nasogastric tube, passed with caution and possibly in conjunction with endoscopy to pass tube at the level of the perforation), gastrostomy, jejunostomy, or parenteral nutrition
  - antibiotics

Outcome: Average number of esophageal repair attempts per patient: 1.54. 86% required just 1 operation. Average time to oral intake is 30 days (conservative management used alone averaged 68 days).[40] 4% mortality.

Recurrent laryngeal nerve paralysis

Heralded by breathy voice, hoarseness, or aspiration. Refer to ENT for endoscopy to determine if vocal cord is paralyzed and its position. 4 possible positions: 1) median, 2) paramedian, 3) intermediate, 4) lateral (cadaveric). Many patients can compensate for median or paramedian position.

Patients requiring intervention are usually treated with medialization techniques, either 1) injection, or 2) medialization thyroplasty using an implant. For injections, different materials may be selected for desired duration of effect. Early intervention may be employed with temporary materials. If no spontaneous recovery after 1 year, injection with Teflon is essentially permanent

Pseudarthrosis (or pseudoarthrosis) following ACDF

Pseudarthrosis may occur with or without supplemental anterior cervical plating.

Practice guideline: Assessment of subaxial fusion

> 2 mm movement between spinous processes on dynamic (flexion-extension) cervical spine X-rays is recommended as a criterion for pseudarthrosis (Level B Class II); this measurement is unreliable when performed by the treating surgeon (Level C Class II).[44]

Visualization of bone trabeculation across the fusion on static films is a less reliable marker for fusion (Level D Class III) (2D reformatted CT increases the accuracy (Level D Class III)).[44]

Incidence: Difficult to assess because of lack of validated criteria. Estimate: 2–20%. Higher with dowel technique (Cloward) than with keystone technique of Bailey & Badgley or with interbody method of Smith-Robinson (10%) or with non-fusion advocated by Hirsch. One criterion: motion > 2 mm between the tips of the spinous processes on lateral flexion/extension X-rays.[45,46] Other criteria that are specific but not sensitive: lucencies around the screws of an anterior plate, toggling of the screws on flexion/extension X-rays.

Presentation: Not uniformly associated with symptoms or problems.[45,47] Some patients may have chronic or recurrent neck pain, some may present with radicular symptoms. (NB: when DePalma's data is analyzed with patients reclassified as failures if neck and/or arm symptoms persist, the success rate of surgery is lower with pseudarthrosis.[48])

Management: Guidelines are shown in **Practice guideline: Management of anterior cervical pseudarthrosis** (p. 1290). No treatment is required for *asymptomatic* pseudarthrosis. Options for symptomatic patients include re-resection of the bone graft with repeat fusion[49] (some recommend using autologous bone if allograft was used; a plate may be considered if one was not used previously), cervical corpectomy with fusion,[49] or posterior cervical fusion.

Practice guideline: Management of anterior cervical pseudarthrosis

Revision of symptomatic pseudarthrosis should be considered (Level D Class III).[50] Posterior approaches may be associated with higher fusion rates on revision than anterior approaches (Level D Class III)[50]

Cervical disc arthroplasty

An alternative to fusion. Uses an artificial disc to preserve motion at the level of the discectomy. Some of the available cervical disc replacement (CDR) models are shown in ▶ Table 77.2.[51]

Table 77.2 Artificial cervical discs

Trade name	Manufacturer	Material	IAR[a]	Comment
Prestige®	Medtronic	MOM[a] (chrome cobalt stainless steel)	variable ball in trough	significant MRI artifact
Prestige® LP	Medtronic	MOM[a] (metal ceramic composite)	variable ball in trough	FDA approved for 1 or 2 levels
Bryan®	Medtronic	lubricated elastic nucleus sealed in a flexible membrane	variable in center of disc space	
ProDisc-C	Centinel Spine	metal-on-polyethylene	posterior part of inferior VB	midline keel inserts into VB; lots of MRI artifact
Mobi-C®	LDR Spine	metal-on-polyethylene	variable in center of disc space	FDA approved for 1 or 2 levels
PCM®	Nuvasive	metal-on-polyethylene	gliding motion	contoured to endplates
Secure-C®	Globus medical	metal-on-polyethylene	15° flex/ext, 10° lateral bending, unconstrained rotation	serrated keels with titanium spray coating

[a] Abbreviations: IAR = instantaneous axis of rotation; MOM = metal-on-metal; PCM = Porous-coated Motion.

Contraindications: described by the FDA have included: isolated axial neck pain, ankylosing spondylitis or pregnancy, rheumatoid arthritis, autoimmune disease, diffuse idiopathic skeletal hyperostosis, severe spondylosis with bridging osteophytes or ossification of the posterior longitudinal ligament, disc height loss > 50%, spinal infection, metal allergy to components of the prosthesis, severe osteoporosis/osteopenia, active malignancy, metabolic bone disease, trauma, segmental instability, 3 or more levels requiring treatment, insulin-dependent diabetes mellitus, human immunodeficiency virus, hepatitis B/C, morbid obesity, absence of motion (< 2 degrees), and posterior facet arthrosis.

Practice guideline: Cervical disc arthroplasty

Cervical arthroplasty is a recommended alternative to ACDF in selected patients for control of arm and neck pain (Level B Class II)[18]

Booking the case: Cervical disc arthroplasty

Also see defaults & disclaimers and/or more significant (p. 25).

1. position: supine, some use halter traction with this
2. equipment:
   a) microscope (not used by all surgeons)
   b) C-arm
3. implants: schedule vendor to provide desired artificial disc. Bail out implants (cages and plates) should also be available in case the artifical disc cannot be implanted
4. neuromonitoring: (optional) some surgeons use SSEP/MEP
5. consent (in lay terms for the patient—not all-inclusive):
   a) procedure: surgery through the front of the neck to remove the degenerated disc and bone spurs, and to place an artificial disc
   b) alternatives: nonsurgical management, surgical fusion (from the front or the back of the neck)
   c) complications: swallowing difficulties are common but usually resolve, hoarseness of the voice (< 4% chance of it being permanent), injury to: foodpipe (esophagus), windpipe (trachea), arteries to the brain (carotid) with stroke, spinal cord with paralysis, nerve root with paralysis, possible seizures with MEPs (if used). The disc may eventually wear out and further surgery may be needed. It is possible that the artifical disc cannot be implanted, in which case a fusion may be necessary

Post-op orders:

1. no cervical collar (the goal is to preserve motion at the operated level)
2. NSAIDs around the clock for ≈ 2 weeks (this theoretically inhibits bone growth which helps avoid undesirable fusion at the operated level)

Technical pointers: The approach and spine work are similar to an ACDF (p. 1284), with the following modifications:

1. positioning: keep the neck in neutral position. Avoid neck extension which narrows the posterior disc space and can increase the difficulty of inserting the prosthesis
2. the height of the artificial disc should be snug, but should not distract the VBs because this can compromise the function of the disc flexing and extending (don't overstuff the disc space)
3. since you are not "jacking up" the disc space with a cage, you have to be extra-meticulous in the foraminal decompression
4. some surgeons wax all decorticated bone surfaces to prevent fusion
5. avoid aggressively removing cartilaginous endplates, or else fusion is more likely to occur
6. NSAIDs are often prescribed for at least 2 weeks post-op since they help inhibit bone growth

Posterior cervical decompression (cervical laminectomy)

Not necessary for unilateral radiculopathy (use either ACD or keyhole laminotomy). Consists of removal of cervical lamina (laminectomy) and spinous processes in order to convert the spinal canal from a "tube" to a "trough."

Usually reserved for the following conditions:

1. multiple cervical discs or osteophytes (anterior cervical discectomy (ACD) is usually used to treat only 2, or possibly 3, levels without) with myelopathy
2. where the anterior pathology is superimposed on cervical stenosis, and the latter is more diffuse and/or more significant (p. 1296)
3. in professional speakers or singers where the 4% risk of permanent voice change due to recurrent laryngeal nerve injury with ACD may be unacceptable

Booking the case: Cervical laminectomy

Also see defaults & disclaimers (p. 25).

1. position: prone, some use pin headholder
2. equipment:
   a) C-arm
   b) high-speed drill
3. implants: cervical lateral mass screws and rods if fusion is being done

4. neuromonitoring: some surgeons use SSEP/MEP
5. consent (in lay terms for the patient—not all-inclusive):
    a) procedure: surgery through the back of the neck to remove the bone over the compressed spinal cord and nerves and possibly to place screws and rods to fuse the bones together
    b) alternatives: nonsurgical management, surgery from the front of the neck, posterior surgery without fusion, laminoplasty
    c) complications: nerve root weakness (C5 nerve root is the most common), may not relieve symptoms, further surgery may be needed, possible seizures with MEPs. If fusion is not done, there is a risk of progressive bone slippage, which would require further surgery

Posterior keyhole laminotomy

AKA "keyhole foraminotomy." First described in 1951.[52] A technique to decompress only individual nerve roots (but not the spinal cord) by creating a small "keyhole" in the lamina to access the nerve root.

Practice guideline: Cervical laminoforaminotomy

Cervical laminoforaminotomy is recommended as a surgical treatment option for symptomatic cervical radiculopathy caused by disc herniation or lateral recess narrowing (Level D Class III).[53]

Indications for keyhole approach (as opposed to anterior discectomy):

1. monoradiculopathy with posterolateral *soft* disc sequestration (small *lateral* osteophytic spurs may also be addressed). This approach does *not* provide adequate decompression with central or broad-based disc herniation or with stenosis of the spinal canal
2. radiculopathy in patients who are professional speakers or singers where the risk of recurrent laryngeal nerve injury is untenable (see above)
3. for lower (e.g., C7, C8, or T1) or upper (e.g., C3 or C4) cervical nerve root compression, especially in a patient with a short thick neck, an anterior approach is more difficult
4. in patients with a herniated disc when it is desired to avoid a fusion (as would be done with an anterior approach)

Booking the case: Cervical keyhole laminectomy

Also see defaults & disclaimers (p. 25).

1. position: prone, some use pin headholder
2. equipment:
    a) microscope (not used by all surgeons)
    b) C-arm
3. instrumentation: some surgeons use a tube retractor system
4. neuromonitoring: some surgeons use SSEP/MEP
5. consent (in lay terms for the patient—not all-inclusive):
    a) procedure: surgery through the back of the neck to remove the bone over the compressed nerve root and possibly remove fragment of herniated disc
    b) alternatives: nonsurgical management, surgery from the front of the neck, posterior surgery with fusion
    c) complications: nerve root injury; may not relieve symptoms, necessitating further surgery; possible seizures with MEPs

Technique

See references.[54,55,56]

Position:

a) prone, on chest rolls. Adhesive tape is used to retract shoulders down for any level below about C4–5. The head is stabilized on a horseshoe headrest or in a Mayfield head holder.
b) sitting position: generally abandoned. However, may be used with proper precautions (p. 1737)

“Open” keyhole foraminotomy

The desired level is localized with intra-op fluoroscopy before making the skin incision, a 2–3 cm midline incision is adequate. A unilateral exposure suffices. Periosteal elevators are used to dissect muscles off the lamina and facet joint in the subperiosteal plane. A Kocher clamp may be placed on the spinous process to permit confirmation of the correct level on intraoperative X-ray. A Scoville retractor or equivalent is employed.

A high-speed drill (e.g., with diamond burr) is used to make an opening in the medial one-third to one-half of the inferior facet of the vertebra above the desired disc space, extending slightly medially into the junction with the lamina. Once the inferior facet is penetrated, the superior facet of the inferior vertebral level will be visualized. This is also thinned with the drill (it is critical to remove the bone of the superior facet of the level below caudally to where it meets the pedicle). A small Kerrison rongeur may be used to slightly enlarge the laminectomy. An opening is made in the ligamentum flavum overlying the lateral aspect of the spinal cord dura. The nerve root can be identified as it exits from the thecal sac, and can be followed as it travels between the pedicles of the vertebrae above and below. Soft tissues (including ligamentum flavum) form fibrous bands across the dorsum of the nerve, and are removed to further expose the dura of the nerve root. The venous plexus around the nerve root is coagulated with bipolar cautery and then divided to mobilize the nerve. The nerve may then be gently moved a few millimeters rostrally using a micro nerve hook. The dura overlying the spinal cord should not be manipulated, and the disc space need not be entered. Inspection for free disc fragments should begin in the nerve root axilla using a probe (e.g., blunt nerve hook). Next, the space anterior to the root (the region of the disc) may be palpated. Any disc fragments that are dislodged are removed with a small pituitary rongeur. If the disc fragment is contained anterior to the posterior longitudinal ligament (PLL), the PLL may be incised in the region of the nerve root axilla with a #11 scalpel blade in a motion that is directed downward and laterally, away from the nerve root and spinal cord. The foraminotomy may be extended slightly laterally if the foramen still feels tight when probed. Small osteophytes can potentially be reduced using a small reverse-angled curette, although some surgeons believe that the need for this is obviated by the decompression provided by the keyhole opening. In some cases, simple posterior decompression of the nerve root (without removing a disc fragment) may be adequate to relieve compression. Spinal stability is usually preserved if less than half the facet joint is removed.

MIS keyhole foraminotomy

Positioning as described above.

1. skin incision
    a) use fluoro to locate the correct level for the incision
    b) incision 1 cm off midline on the side of the pathology at the level of the disc space
    c) remove adhesive plastic barrier (e.g., Ioban®) from around the opening to prevent pieces from being dragged into the incision
2. avoid using a guidewire to reduce the risk of penetrating the interlaminar space. STAY LATERAL and insert the thinnest dilator. Dock the dilator on the lateral mass and insert progressively sized dilators
3. use Bovie to expose lateral lamina and medial facet joint. Start laterally where bone is more easily felt and there is little danger of penetrating the interlaminar space and injuring the spinal cord
4. use a straight curette to expose the inferior edge of the superior lateral lamina and the medial facet joint
5. drill off the medial inferior facet, to expose the superior facet of the level below
6. drill the medial superior facet until you are flush with the superior aspect of the pedicle below
7. this completes the bony work, the soft tissue work proceeds as above under open keyhole foraminotomy

Outcome

A number of large series have reported good or excellent outcome in the range of 90–96%.[55]

78 Cervical Degenerative Disc Disease and Cervical Myelopathy

78.1 Cervical disc degeneration – general information

Cervical degenerative disc disease is generally discussed in terms of "cervical spondylosis," a term which is sometimes used synonymously with "cervical spinal stenosis." Spondylosis usually implies a more widespread age-related degenerative condition of the cervical spine including various combinations of the following:

1. congenital cervical spinal stenosis (the "shallow cervical canal"[1])
2. degeneration of the intervertebral disc producing a focal stenosis due to a "cervical bar," which is usually a combination of:
    a) osteophytic spurs ("hard disc" in neurosurgical jargon)
    b) and/or protrusion of intervertebral disc material ("soft disc")
3. hypertrophy of any of the following (which also contributes to canal stenosis):
    a) lamina
    b) dura
    c) articular facets
    d) ligaments, including
        - increased stenosis in extension is more common than with flexion (based on MRI studies[2] and cadaver studies), largely due to posterior inbuckling of ligamentum flavum[3]
        - posterior longitudinal ligament: may include ossification of the posterior longitudinal ligament (OPLL) (p. 1370).[4] May be segmental or diffuse. Often adherent to dura
        - ossification of the ligamentum flavum[5] (yellow ligament)
4. subluxation: due to disc and facet joint degeneration
5. altered mobility: severely spondylotic levels may be fused and are usually stable; however, there is often hypermobility at adjacent or other segments
6. telescoping of the spine due to loss of height of VBs and discs → "shingling" of laminae
7. alteration of the normal lordotic curvature[6] (NB: the amount of abnormal curvature did not correlate with the degree of myelopathy)
    a) reduction of lordosis: including
        - straightening
        - reversal of the curvature (kyphosis): may cause "bowstringing" of the spinal cord across osteophytes
    b) exaggerated lordosis (hyperlordosis): the least common variant (may also cause bowstringing)

78.2 Pathophysiology

Pathogenesis is controversial. Theories include the following alone or in combination:

1. direct cord compression between osteophytic bars and hypertrophy or infolding of the ligamentum flavum, especially if superimposed on congenital narrowing or cervical subluxations
2. ischemia due to compression of vascular structures[7] (arterial deprivation[8] and/or venous stasis[9])
3. repeated local cord trauma by normal movements in the presence of protruded discs and/or osteophytic (spondylotic) bars (cord and root injuries[10])
    a) cephalad/caudad movement with flexion extension[11]
    b) anterior/posterior traction on the cord by dentate ligaments[12] & nerve roots
    c) diameter of spinal canal varies during flexion and extension
        - increased stenosis is more common in extension (see above)
        - unstable segments may sublux (so-called pincer mechanism)[13]

Histologically,[14] there is degeneration of the central gray matter at the level of compression, degeneration of the posterior columns above the lesion (particularly in the anteromedial portion), and demyelination in the lateral columns (especially the corticospinal tracts) below the lesion. Anterior spinal tracts are relatively spared. There may be atrophic changes in the ventral and dorsal roots and neurophagia of anterior horn cells.

78.3 Epidemiology/Natural history

9% of individuals > 70 years of age had clinically significant cervical spinal stenosis (CSS) (including degenerative stenosis and OPLL) in a cadaveric study.[15]

23% of patients with CSS developed myelopathy with mean follow-up of 44 years.[16] This number is even lower in patients without radiculopathy or electrodiagnostic evidence of nerve root involvement (including prolonged SEPs and MEPs) on presentation (Class I).[16,17]

Patients with CSS without myelopathy who have T2 signal changes on MRI are at increased risk of developing myelopathy in the *long term* (> 1 year).[16]

Once myelopathy is detected, the time course of symptoms is highly variable and unpredictable. In ≈ 75% of cases of cervical spondylotic myelopathy (CSM), there is progression either in a stepwise fashion (in one–third) or gradually progressive (two–thirds).[18] In some series, the most common pattern was that of an initial phase of deterioration followed by a stabilization that typically lasts for years and may not change thereafter.[19,20] In these cases, the degree of disability may be established early in the course of CSM. Others disagree with such a "benign" outlook and cite that over 50% of cases continue to deteriorate with conservative treatment.[21] Sustained spontaneous improvement is probably rare.[22]

In patients < 75 years of age and mJOA score (p. 1299) > 12, the clinical condition remained stable in 3 years of follow-up (Class I)[17] (however, these patients can still have significant disability that can respond to surgery). Longstanding myelopathy with severe stenosis over many years may cause irreversible deficit due to necrosis in gray and white matter (Class III).[17]

78.4 Clinical

78.4.1 General information

Cervical spondylosis is a condition that may produce several types of clinical problems[23]:

1. myeloradiculopathy: some combination of
   a) radiculopathy: nerve root compression may cause nerve-root (radicular) complaints
   b) spinal cord compression may cause myelopathy (see stereotypical myelopathic syndromes (p. 1299))
2. pain and paresthesias in the head, neck, and shoulders with little or no suggestion of radiculopathy nor abnormal physical findings. This group is the most difficult to diagnose and treat, and often requires a good physician-patient relationship to decide if surgical treatment should be undertaken in an attempt to provide relief

Cervical spondylosis is the most common cause of myelopathy in patients > 55 yrs of age.[22] CSM is rare in patients < 40 years of age.

CSM develops in almost all patients with ≥ 30% narrowing of the cross-sectional area of the cervical spinal canal[24] (although some patients with more severe cord compression do not have myelopathy[25,26]).

Gait disturbance, often with LE weakness or stiffness, is a common early finding in CSM.[27] Ataxia may result from spinocerebellar tract compression. Early on, patients may experience difficulty running. Cervical pain and mechanical signs are uncommon in cases of pure myelopathy. See ▶ Table 78.1 for the frequency of symptoms in CSM in one series. In most cases the disability is mild, and the prognosis for these is good.

78.4.2 Motor

Findings can be due to cord (UMN) and/or root (LMN) compression. The earliest motor findings are typically weakness in the triceps and hand intrinsics.[29] There may be wasting of the hand muscles.[30] Slow, stiff opening and closing of the fists may occur.[31] Clumsiness with fine motor skills (writing, buttoning buttons…) is common.

There is often *proximal* weakness of the lower extremities (mild to moderate iliopsoas weakness occurs in 54%) and spasticity of the LEs.

78.4.3 Sensory

Sensory disturbance may be minimal, and when present is often not radicular in distribution. There may be a glove-distribution sensory loss in the hands.[32] A sensory level (i.e., a demarcation below which there is a sensory loss) may occur a number of levels below the area of cord compression.

Table 78.1 Frequency of symptoms in CSM (37 cases[28])

Finding	%
pure myelopathy	**59**
myelopathy + radiculopathy	**41**
reflexes	
• hyperreflexia	87
• Babinski	54
• Hoffman	13
sensory deficits	
• sensory level	41
• posterior column	39
• dermatomal arm	33
• paresthesias	21
• positive Romberg	15
motor deficits	
• arm weakness	31
• paraparesis	21
• hemiparesis	18
• quadriparesis	10
• Brown-Séquard	10
• muscle atrophy	13
• fasciculations	13
pain	
• radicular arm	41
• radicular leg	13
• cervical	8
spasticity	**54**
sphincter disturbance	**49**
cervical mechanical signs	**26**

LEs often exhibit loss of vibratory sense (in as many as 82%), and occasionally have reduced pinprick sensation (9%) (almost always restricted to below the ankle). Compression of the spinocerebellar tract may cause difficulty running. Lhermitte's sign (p. 1712) was present in only 2 of 37 cases. Some patients may present with a prominence of posterior column dysfunction (impaired joint position sense and 2-point discrimination).[33]

78.4.4 Reflexes

In 72–87%, reflexes are hyperactive at a varying distance below the level of stenosis. Clonus, Babinski's sign (p. 91), or Hoffman's sign (p. 91) may also be present. Dynamic Hoffman's sign[34] may be more sensitive: test for Hoffman's sign during multiple cervical flexion and extension movements as tolerated by the patient. 94% of asymptomatic individuals with Hoffman's reflex will have significant spinal cord compression on MRI.[35] Inverted radial reflex: flexion of the fingers in response to eliciting the brachioradialis reflex, said to be pathognomonic of CSM.[36]

A hyperactive jaw jerk indicates upper motor neuron lesion *above* the midpons, and distinguishes long tract findings due to pathology above the foramen magnum from those below (e.g., cervical myelopathy): not helpful if absent (a normal variant). Primitive reflexes (grasp, snout, rooting) are not reliable localizing signs (except perhaps the grasp reflex) of frontal lobe pathology.

78.4.5 Sphincter

Urinary urgency and frequency are common in CSM; however, these complaints are also protean in the aging population. Urinary incontinence is rare. Anal sphincter disturbances are uncommon.

78.4.6 Cervical spondylotic myelopathy syndromes

Clustering of CSM into these 5 clinical syndromes has been described[31]:

1. transverse lesion syndrome: involvement of corticospinal and spinothalamic tracts and posterior columns, with anterior horn cells *segmentally* involved. Most frequent syndrome, possibly an “end-stage” of the disease process
